Tooth numbering systems enable clinicians to more effectively communicate unequivocally about a patient's teeth. In the United States, the Universal Numbering System (Figure 17–6) is used, which assigns the uppercase letters A through T for primary teeth and the numbers 1 through 32 for permanent teeth. The initial designation begins on the upper right, most posterior tooth and continues along the upper teeth to the left side. The count then drops to the lower, most posterior tooth on the left side and continues along the bottom teeth to end on the lower right side.

A common international tooth numbering system adopted by the FDI World Dental Federation is the ISO 3950 notation. This two-digit system designates numbers 1 through 4 to each permanent tooth quadrant (upper right is 1, upper left is 2, lower left is 3, and lower right is 4), and numbers 1 through 8 to teeth of the permanent dentition (central incisors are 1s, lateral incisors are 2s, canines are

\[\text{Figure 17–6. Universal numbering system for primary and permanent dentition.}\]
3s, etc., up through third molars which are 8s), resulting in a two-digit combination of the quadrant and tooth. For example, the upper right and left central incisors would be notated 11 and 21, respectively, communicated as “one-one” or “two-one.” Similar designations are used in the primary dentition, with quadrants assigned numbers 5 through 8 and primary teeth assigned numbers 1 through 5.

**Eruption Symptoms**

Many symptoms are ascribed to the process of tooth eruption or teething. However, any temporal association with fever, upper respiratory infection, or systemic illness is coincidental rather than related to the eruption process. Attributing fever to teething without a thorough diagnostic evaluation for other sources has resulted in missing serious organic disease.

Common therapies for teething pain include the application of over the counter teething gels or liquids. In children less than 2 years of age, their main ingredient, benzocaine, can cause the rare, but sometimes serious condition of methemoglobinemia. While “natural” benzocaine-free formulations are available, systemic analgesics such as acetaminophen or ibuprofen are safer and more effective. Chewing on a teething object can be beneficial, if only for distraction purposes.

Occasionally, swelling of the alveolar mucosa overlying an erupting tooth can be seen. This usually asymptomatic condition appears as localized red to purple, round, raised, and smooth lesion. Treatment is rarely needed as these eruption cysts/hematomas resolve with tooth eruption.

**Pathologies of Tooth Eruption**

### Natal Teeth

On rare occasions (1:3000), natal teeth are present at birth and neonatal teeth erupt into the oral cavity within the first month of life. These are most commonly (85%) primary mandibular incisors. A radiograph should be taken to determine whether they are regular or supernumerary teeth (10%). Although the preferred approach is to leave the tooth in place, natal teeth that are supernumerary, hypermobile, or of inferior structural quality should be extracted. Other indications for removal of natal teeth include nursing difficulties and if the sharp incisal edges of these teeth cause laceration of the ventral surface of the infant’s tongue (Riga-Fede disease).

### Delayed Eruption

Premature loss of a primary tooth can either delay or accelerate eruption of the underlying permanent tooth. Accelerated eruption occurs when the primary tooth is removed within 6–9 months of its normal exfoliation, but loss of the primary tooth more than 1 year before its expected exfoliation typically delays eruption of its successor. The loss of a primary tooth often causes adjacent teeth to tip or drift into the resulting space, leading to space loss for the underlying permanent tooth. Placement of a space maintainer can prevent such space loss.

Other local factors delaying or preventing tooth eruption include supernumerary teeth, cysts, odontogenic tumors, over-retained or ankylosed primary teeth, and impacted teeth. A generalized delay in eruption may be associated with global developmental delays, endocrinopathies, and other systemic conditions.

#### Ectopic Eruption

Insufficient space in the dental arch may cause permanent teeth to erupt ectopically and result in a usually painless root resorption of the adjacent primary tooth. This phenomenon is observed most commonly with the maxillary first permanent molars.

Occasionally, mandibular incisors erupt lingually and lead to over-retention of the primary predecessor, resulting in a “double row of teeth.” If the primary tooth is still firmly in place, the dentist should remove it to allow its successor to drift into proper position.

#### Impaction

Impaction occurs when a permanent tooth is prevented from erupting. Although crowding is a frequent reason, over-retained primary or supernumerary teeth are other causes. The teeth most often affected in the developing dentition are the maxillary incisors and canines. Often, they are brought into correct alignment by early extraction of the preceding or adjacent primary teeth. If this approach is ineffective, surgical exposure of the impacted tooth and orthodontic treatment are indicated.

#### Variations in Tooth Number

Tooth agenesis is rare in the primary dentition, but occurs with an incidence of 5% in the permanent dentition. The most frequently missing teeth are the third molars followed by the mandibular second premolars and maxillary lateral incisors. Oligodontia, a condition in which only a few teeth develop, occurs in patients with ectodermal dysplasias. Tooth agenesis is caused by several independent defective genes, which can act alone or in combination with other genes. It can occur as an isolated problem, but is common in combination with cleft lip/cleft palate or as part of the phenotype of over 200 syndromes.

Occasionally, supernumerary teeth are present. If they are in the maxillary incisor midline area they are called mesiodentes. Their removal is recommended especially if they hinder eruption of adjacent permanent incisors.

DENTAL CARIES

Dental caries is the most common chronic disease of childhood and the most prevalent unmet health need of US children. Largely a disease of poverty, dental caries affects almost 80% of children and adolescents living in low-income families.

Early Childhood Caries

Formerly termed “baby bottle tooth decay” or “nursing bottle caries,” early childhood caries is a particularly virulent and rapidly progressive form of caries that begins on the smooth surfaces of the teeth soon after eruption. ECC is defined as one or more decayed (d), missing (m), or filled (f) tooth surfaces (s) in any primary tooth in a child under 6 years of age. The disease typically involves the maxillary incisors, but any other teeth may be affected. A lack of adequate preventive care and poor feeding habits can place children at high risk for ECC.

Any sign of smooth-surface caries in a child less than 3 years is termed severe ECC (S-ECC). From 3 to 5 years, a dmfs score of 1 or more in maxillary front teeth or a total dmfs score of 4 or higher must be present to make a diagnosis of S-ECC. Children with S-ECC are at higher risk for new carious lesions. They are also likely to experience frequent hospitalizations, emergency department visits, and school absences due to the severity of existing carious lesions. The presence of S-ECC can also result in below-normal height and weight gain and diminished oral health-related quality of life for the affected child. Although S-ECC can affect all children, it is 32 times more likely in children who consume sugary foods and whose mothers are of low socioeconomic status and education level.

Pathogenesis

Development of caries requires the interaction of four factors: (1) a host (tooth in the oral environment); (2) a suitable dietary substrate (fermentable carbohydrates); (3) cariogenic microorganisms that adhere to the tooth; and (4) time, measured as the frequency of exposure to fermentable carbohydrates and the duration of acid exposure. The main organisms implicated in the initiation of caries are MS and Streptococcus sobrinus. Lactobacillus acidophilus and Lactobacillus casei are also linked to the progression of caries. MS organisms are most commonly passed from mother to child. A “window of infectivity” between ages 19 and 30 months has been described, but MS colonization of the oral cavity can occur as early as 3 months of age. Earlier colonization increases the risk of caries.

Dental plaque is an adherent biofilm on the tooth surface that harbors acidogenic bacteria in close proximity to the enamel. As bacteria metabolize sucrose, they produce lactic acid that solubilizes calcium phosphate in tooth enamel. Demineralization of the dental enamel occurs below pH 5.5 and is the first step in cariogenesis. The flow rate of saliva and its buffering capacity are important modifiers of demineralization. Demineralization of enamel and dentin can be halted or even reversed by redeposition of calcium, phosphate, and fluoride from saliva.

If caries progresses it penetrates the enamel, advancing through the dentin toward the pulp of the tooth. In response, blood vessels in the pulp dilate and inflammatory cells begin to infiltrate (pulpitis), resulting in tooth pain. When the carious lesion is still untreated, pulp invasion will occur, triggering invasion of more inflammatory cells and the eventual formation of a small pulpal abscess. Once the pulp in the root of the tooth becomes necrotic, a periapical abscess develops (Figure 17–7) which usually causes severe pain, fever, and swelling.

Caries Prevention

Prevention of dental caries necessitates restoration of the delicate balance between pathologic and protective factors. Pathologic factors include cariogenic bacteria and fermentable carbohydrates. Protective factors include salivary flow and fluoride in food, beverages, drinking water, and oral care products. Saliva contains calcium, phosphate, proteins, and antibacterial substances; it also buffers acid produced by bacteria in plaque.
The concept of prevention through timely and regular parent education, early diagnosis, and prompt intervention offers greater efficiency, better health outcomes, and lower costs than repeated restoration of diseased teeth. In this regard, the primary care physician plays an invaluable role since parents are more likely to take their very young child to a physician for well-child visits than to a dentist for oral health counseling. Some states have established formal programs to entice medical offices to provide preventive dental services that include dental screening, caries risk assessment, parent counseling about their child’s oral health, and referrals to dentists as needed.

**Dietary Counseling**

The development of dental caries requires frequent exposure to fermentable carbohydrates. Poor feeding habits that place children at higher risk for ECC include the frequent consumption of sugar-containing beverages from a nursing bottle, frequent sipping from a no-spill sippy cup, taking a bottle to bed, and frequent ad libitum breast-feeding. Each such exposure produces an acidic oral environment for up to 30 minutes and propagates the caries process.

Infants should be weaned from the bottle between 12 and 18 months of age and encouraged to drink from an uncovered cup (rather than a no-spill training cup). Parents must also be advised to limit the frequency of their child’s consumption of sugar-containing snacks between meals. As parents are involved in helping feed their child at the infant and toddler stages of development, they should be counseled to eliminate saliva-sharing activities (eg, sharing spoons during meals) to minimize the transmission of cariogenic bacteria.

**Oral Hygiene**

Oral hygiene practices must start soon after birth and counseling in this area should involve both parent and patient. The infant’s gums can be cleaned daily using a moist, soft cloth prior to tooth eruption. Once the teeth erupt, oral hygiene must be practiced in earnest, particularly in high-risk children. Due to a lack of manual dexterity in children younger than 8 years of age, parents need to brush for them twice daily and assist with flossing if their child’s teeth are tightly contacting each other.

**Fluorides**

Fluorides are safe and effective in caries prevention through three topical and systemic mechanisms of action. By both routes of administration fluorides can affect the dentin and enamel of erupted and unerupted teeth. Topical application inhibits bacterial metabolism by interfering with enzyme activity; inhibiting demineralization; and enhancing remineralization. Systemic benefits are achieved by oral ingestion from sources such as fluoridated drinking water, beverages, infant formulas, and prepared food. Recently, the US Department of Health and Human Services proposed a lower limit of 0.7 ppm for fluoride levels in community water supplies to balance the benefits of preventing dental caries while minimizing the risk for enamel fluorosis. Since fluorosis is associated with cumulative fluoride intake during enamel development, the severity of the condition is dependent on the dose, duration, and timing of the oral intake of fluoride containing products. Infants who consume concentrated infant formula as the main source of nutrition are at an increased risk for enamel fluorosis in the permanent dentition if fluoride-containing formulas are reconstituted with fluoridated drinking water.

Fluoride supplements also help reduce dental caries prevalence and are a consideration for children at high caries risk who drink fluoride-deficient (< 0.6 ppm fluoride ion) water. Factors associated with a high caries risk include orthodontic appliances, decreased salivary function, gastrointestinal reflux disease, a cariogenic diet, physical inability to properly clean the teeth, mother or siblings with caries, and personal history of caries. However, as recommended by the American Dental Association, a child’s true exposure to all sources of fluoride must be thoroughly evaluated before supplements are prescribed so as to avoid enamel fluorosis.

The judicious use of fluoride-containing toothpastes and mouth rinses for children reduces dental caries prevalence in the primary and permanent dentition. Since children younger than 6 years of age cannot expectorate reliably and lack appropriate dexterity for proper brushing, parents must monitor the use of fluoridated toothpaste at each brushing, ensuring that only a “smear layer” (< age 3) or “pea-sized” amount (3–6 years of age) of dentifrice is used to reduce the risk for fluorosis. The beneficial effect of fluoride containing toothpaste can be maximized by brushing teeth twice daily and either avoiding or rinsing minimally after brushing.

**Fluoride Varnish for High-Risk Populations**

Applications of fluoride varnish during well-child visits with physicians is successful in reducing dental caries among vulnerable children (ICD-10-CM Diagnosis Code Z29.3: Encounter for Prophylactic Fluoride Administration). The sticky nature of the varnish’s resin base allows for extended contact time of its fluoride content with the tooth surface.

The varnish in single-dose packages (0.3–0.5 mL) should be stirred before application and the contents of larger tubes (5 mL) massaged to dissolve any precipitated fluoride. The former are preferable because consistent availability of fluoride cannot be guaranteed with multi-dose packages. The average amount of varnish needed depends on the number of teeth present and ranges from 0.1 mL for infants to 0.3 mL for preschool children. Teeth should be dried with gauze before the varnish is applied with a small brush. It will set.
quickly to a dull yellow film upon contact with saliva. Caregivers should be instructed not to brush or floss and to give their children only soft foods until the next morning to provide enough time for absorption of the fluoride into enamel.

**Other Adjunctive Measures**

Xylitol containing products are marketed in many forms (eg, gums, mints, lollipops, chewable tablets, toothpastes, mouthwashes) as an adjunctive measure in caries prevention. Xylitol is considered a noncariogenic substitute due to the inability of oral bacteria to metabolize this five-carbon sugar alcohol. However, recent systematic reviews suggest that there is limited evidence for caries reduction from xylitol-containing products.

### Treatment of Caries

Caries is usually diagnosed by visual and tactile oral examination supplemented by radiographs to detect caries on the surfaces between teeth. The initial defect observed on enamel beneath dental plaque is the so-called “white-spot lesion,” a white, chalky, decalcified area along the gingival margin or on approximated tooth surfaces. Frank carious lesions are light- to dark-brown spots or cavities of varying size on the tooth. A light shade of brown indicates rampant decay, while arrested caries is almost black in color.

In the early stages of decay, the tooth may be sensitive to temperature changes or sweets. Removing the carious tooth structure and filling the early defect with a restorative material can repair the tooth. As decay progresses deeper into the pulp, inflammation and pain increase. Eventually, the entire pulp becomes necrotic, and a choice must be made between root canal therapy (pulpectomy) and removal of the tooth. In the presence of cellulitis, extraction, and antibiotic therapy are the treatments of choice.

When restorative materials are used to repair a tooth, the primary choices include dental amalgam, composite resin, or glass ionomer cement. For primary molars with extensive caries and/or pulpal involvement, full coverage crowns are the restorations of choice and these are available as preformed stainless steel crowns and in various cosmetic iterations.

Silver diamine fluoride has been utilized to slow or arrest caries progression in select patients. Its use may be considered in circumstances where the risk of morbidity or mortality under sedation or general anesthesia outweighs the benefit of definitive restorations. Once applied, the medication produces a gray-black discoloration of carious defects of treated teeth and may be interpreted as caries.

**PERIODONTAL DISEASE**

Periodontal diseases are a group of conditions affecting a tooth’s supporting structures: bone, gingiva, and periodontal ligament (Figure 17–8). Plaque and bacterial accumulation in the gingival sulcus causes a localized inflammation of the gingival tissue adjacent to a tooth. This initial phase, called dental plaque-induced gingivitis, is found almost universally in children and adolescents. This affects about half of the population by 5 years of age and reaches a prevalence of nearly 100% at puberty. Gingivitis is considered reversible, and generally responds well to removal of dental plaque and improved oral hygiene.

Periodontitis, the subsequent phase, is characterized by irreversible loss of the periodontal attachment and destruction of bone. Abnormalities in immune function such as neutrophil chemotaxis, phagocytosis, and antibacterial activity increase the risk of periodontitis. Actinobacillus actinomycetemcomitans in combination with Bacteroides-like species are implicated in this disease process. If hygiene does not improve and local contributing factors are not removed, chronic periodontitis can become more severe, resulting in generalized loss of the periodontal attachment. Chronic periodontitis also responds well to improved oral hygiene and is more easily arrested in its early stages when the development of deep pockets because of attachment loss is gradual. A separate entity known as aggressive periodontitis, previously labeled as early-onset periodontitis, is defined by rapid attachment loss and alveolar bone destruction. Treatment consists of combined surgical and nonsurgical mechanical debridement, and antibiotic therapy.

![Figure 17–8. Periodontal disease.](image-url)
Systemic conditions, hormonal alterations associated with the onset of puberty, certain medications, and malnutrition can intensify the inflammatory response to plaque. Periodontitis as a manifestation of systemic disease is associated with hematological (acquired neutropenia, leukemias) or genetic disorders, such as Down-, Papillo-Lefevre-, Chediak-Higashi-, hypophosphatasia-, and leukocyte adhesion deficiency syndromes. The incidence of necrotizing periodontal diseases is lower (1%) in North America than in developing countries (2%–5%). These diseases are characterized by interproximal ulceration and necrosis of the dental papillae, rapid onset of dental pain, and often fever. Predisposing factors include viral infections, malnutrition, emotional stress, and systemic disease. The condition usually responds well to mechanical debridement, improved oral hygiene, and antibiotic therapy for febrile patients.

DENTAL EMERGENCIES

Orofacial Trauma

Orofacial trauma consists mainly of abrasion or laceration of the lips, gingiva, tongue, or oral mucosa (including the frena), without damage to the teeth. Lacerations should be cleansed, inspected for foreign bodies, and sutured if necessary. Occasionally, radiographs of the tongue, lips, or cheeks are needed to detect tooth fragments or other foreign bodies. All patients with facial trauma should be evaluated for jaw fractures. Blows to the chin are among the most common childhood orofacial traumas. They are also a leading cause of condylar fracture in the pediatric population. Condylar fracture should be suspected if significant pain or deviation occurs when the mouth is opened.

Tooth-related trauma affects the dental hard tissues and pulp, the alveolar process, and the periodontal tissues. The range of dental injuries includes root and coronal fractures, concussion, subluxation, intrusive, extrusive, and lateral luxations, and avulsion. Figure 17–9 demonstrates different degrees of tooth fractures and Figure 17–10 shows the different luxation injuries.

Primary Teeth

The most common injuries in the primary dentition are luxation injuries, with the greatest incidence of trauma occurring between 2 and 3 years of age. Parents should be advised of any permanent tooth complications such as enamel hypocalcification or crown-root dilacerations caused by intrusion injuries of primary maxillary front teeth. An intrusive luxation is usually observed for a period to discern whether the tooth will spontaneously re-erupt (see Figure 17–10) unless the root of the primary tooth is impinging on the crown of the permanent tooth bud. Severe luxation in any direction is treated with extraction. Avulsed primary teeth are rarely replanted. In a root fracture, the crown and apical fragment are generally extracted, but the latter should be left for physiologic resorption if its retrieval would result in potential damage to the permanent tooth.

Permanent Teeth

The most common injury in the permanent dentition is crown fracture occurring secondary to falls, traffic accidents,
violence, and sports. Intrusions of permanent teeth are corrected with repositioning. Lateral and extrusive luxations are generally repositioned and splinted for up to 4 weeks. Root canal treatment is necessary in the majority of cases to prevent inflammatory root resorption and needs to be initiated within 10 days from time of the initial injury.

Because the prognosis for viability worsens rapidly as time outside the mouth increases, an avulsed permanent tooth should be replanted into its socket as soon as possible at or near the accident scene after gentle rinsing with clean water. The patient must seek emergency dental care immediately thereafter. Hank’s balanced salt solution is the best storage and transport medium for avulsed teeth that are to be replanted at a distant site. The next best storage mediums in decreasing order are milk, saline, saliva (buccal vestibule), or water. The commercially available FDA-approved Save-a-Tooth kit should be part of first-aid kits in school and sports facilities.

**Antibiotic Usage**

There is limited evidence for the use of systemic antibiotics for dental injuries; however, antibiotic use remains at the discretion of the clinician as traumatic dental injuries are often accompanied by soft tissue lacerations, maxillofacial trauma, and affect medically compromised patients. For avulsion injuries, tetracycline is the antibiotic of choice for the first week after replantation of an avulsed tooth. However, due to the risk of discoloration in developing permanent teeth, penicillin or amoxicillin can be prescribed as an alternative to tetracycline for children under 12 years of age.

**Odontogenic Infections**

Odontogenic infections can result from carious lesions, periodontal complications, and dental trauma. If left untreated, pain, a dental abscess, and facial cellulitis can result. These sequelae can lead to serious complications such as dehydration from difficulties with eating or drinking, cavernous sinus thrombosis, and Ludwig’s angina. While acetaminophen or ibuprofen can help relieve pain, prompt intervention and removal of the source of infection is needed to avoid adverse sequelae. Topical medications are of limited value for pain relief.

**Alveolar Abscess**

When left untreated, the infection that causes necrosis of the pulp tissue can spread outward from the apical foramen of the root of the tooth through bone and periosteum to produce an alveolar abscess. In its acute form, the abscess presents as a painful and diffuse infection of the gingival soft tissues that requires immediate attention. Treatment includes root canal therapy or extraction for the drainage of pus from the site of infection and for pain relief. A chronic alveolar abscess (or parulis) is a localized smaller swelling confined to the gingival tissue associated with the infected tooth. A parulis does not represent an urgent situation and antibiotic therapy is not warranted as the pus is draining through a fistula tract. Definitive treatment includes root canal therapy or extraction of the offending tooth.

**Facial Cellulitis**

Facial cellulitis results if the odontogenic infection invades the facial spaces. Elevated temperature (> 38.8°C), difficulty swallowing, and difficulty breathing are signs of serious infections. Swelling of the midface—especially the bridge of the nose and the lower eyelid—should be urgently evaluated as a potential dental infection. Depending on the clinical situation and the patient’s overall health, treatment choices range from treating or extracting the offending tooth/teeth, with or without antibiotic coverage, to achieve drainage and eliminate the source of infection. Occasionally, treatment is delayed for several days while antibiotics are administered orally or IV (for hospitalized patients) so that the infection can be properly drained. The first line antibiotic of choice is penicillin and secondarily clindamycin or ampicillin-sulbactam (Unasyn). Hospitalization is a prudent choice for younger children with severe facial cellulitis especially if other risk factors are present—dehydration, airway compromise, or possible noncompliance.

**SPECIAL PATIENT POPULATIONS**

**Oral Conditions**

Children with special health care needs (C-SHCN) may have anomalies affecting their teeth and/or oral soft tissues as a primary manifestation of a systemic condition or secondary to medical interventions. For children with Trisomy 21 for example, conditions such as hypodontia and delayed eruption are considered primary oral manifestations of the syndrome. Rare systemic conditions such as osteogenesis imperfecta can be associated with dentinogenesis imperfecta—a defect affecting the dentin of primary and
permanent dentition resulting in early loss of teeth if left unrecognized and untreated.

Medical interventions such as chemo- and radiation therapy can have immediate and long-term oral effects. Most immediate are xerostomia, particularly where the salivary glands are in the path of the radiation beam, mucositis due to atrophy of the oral mucosa, and severe oral pain from mucositis. Long-term effects include microdantia, hypocalcification, short and blunted roots, and delayed tooth eruption. Patients undergoing hematopoietic stem cell transplantation are at risk for oral fungal and herpes simplex virus infections during the initial engraftment and hematopoietic reconstitution period. Allogeneic transplants further predispose a child to oral graft-versus-host disease, which can cause ulcerations, erosive lesions, or whitish reticulations affecting various oral soft tissues.

### Preventive Measures

Dental caries affects C-SHCN for reasons that can be uniquely related to their medical condition. The long-term use of medications is associated with increased caries risk as some of these contain sucrose as a sweetener. Likewise, the frequent consumption of supplemental nutrition drinks that are typically high in carbohydrates significantly increases the risk for dental caries. Simple preventive steps such as rinsing with fluoridated water or a fluoridated mouth rinse, and/or tooth brushing with fluoridated toothpaste after each medication or supplemental nutrition intake lowers caries risk in such patients. The prescription of sugar-free alternatives for medications is recommended as a preventive measure.

The susceptibility of C-SHCN to periodontal diseases can result from difficulties with performing oral hygiene by the caregiver due to a child’s oral aversions, limited mouth opening, or erratic body movements. Parents may also wrongly choose not to brush their child’s teeth believing it to be unnecessary since the child takes no foods my mouth. G-tube fed children typically exhibit increased calculus build-up due to the lack of mechanical stimulation associated with oral feedings, increasing their risk for periodontal disease.

### Preventive Measures for the Oncology Patient

It is imperative that a dentist who is knowledgeable about pediatric oncology evaluates children with cancer soon after diagnosis. The aims are to (1) develop a dental treatment plan in collaboration with the oncologist prior to cancer therapy; (2) educate the patient and caregivers about the importance of good oral hygiene; and (3) remove all existing and potential sources of dental infection (eg, abscessed teeth, extensive caries) before the child becomes neutropenic from chemotherapy.

Preventive strategies aimed at reducing oral complications from cancer therapy include reduction of refined sugars, fluoride therapy, mucositis prevention, and patient education. Meticulous oral hygiene reduces the risk for severe mucositis. In children receiving radiation therapy, customized fluoride applicators and artificial saliva are used in combination with regular follow-up visits to minimize rapid and extensive destruction of teeth due to xerostomia.

### Dental Treatment Considerations

#### Indications for Antibiotic Prophylaxis

All dental procedures (even tooth brushing) often result in transient bacteremia. Patients with certain medical conditions are at increased risk for bacteremia-induced infections and require prophylactic antibiotic coverage prior to invasive dental procedures. These include children with cardiac conditions such as heart valves, previous infective endocarditis, repaired congenital heart disease with residual defects related to a prosthetic patch, and unrepaired cyanotic congenital heart disease. For nonvalvular devices such as indwelling vascular catheters and cardiovascular implantable electronic devices, antibiotic coverage is only indicated at the time of placement. Hydrocephalus shunts with vascular access (ie, ventriculoatrial, ventriculocardiac, ventriculo-venous) require antibiotic prophylaxis to minimize risk for infection from invasive dental procedures, whereas the nonvascular type (ventriculoperitoneal) does not.

Antibiotic prophylaxis is generally not indicated for dental patients with pins, plates, screws, or other orthopedic hardware that is not within a synovial joint. Likewise, most patients with total joint replacements do not routinely require antibiotic prophylaxis except for the early postsurgical period (6 months).

For immunocompromised patients, the absolute neutrophil count (ANC) is important for the dentist because of the risk for systemic sepsis from dental procedures. The AAPD guideline indicates that at levels above 2000/mm³ antibiotic prophylaxis is not indicated. Between 1000 and 2000/mm³, prophylaxis is subject to clinical judgment of the dentist, the patient’s health status, and the planned procedures. Both the dentist and physician should discuss and plan the need for antibiotic prophylaxis in these unique circumstances.

#### Management of Bleeding Disorders

Oral surgical procedures on any child with a bleeding disorder should be planned in a coordinated approach between the child’s hematologist and dentist. Patients with mild bleeding disorders (eg, mild von Willebrand’s disease) can be treated in the ambulatory dental setting with local hemostatic measures such as topical hemostatic agents (eg, Gelfoam, thrombin). Patients with severe coagulation disorders (eg, severe hemophilia A and/or Factor VIII antibodies)
requiring dental surgery should be admitted to a hospital. Preoperative planning includes prescription of antifibrinolytic medications such as ε-aminocaproic or tranexamic acid to minimize postoperative oral bleeding. Intra-operatively, the placement of topical hemostatic agents within tooth sockets and additional sutures immediately following extractions improves clot formation.

For patients receiving anticoagulation therapy, dosage reduction before dental surgery is generally not recommended as the risk of embolism outweighs the risk for bleeding complications. In these instances, the dentist should consult with the hematologist to obtain the most recent INR and discuss the most appropriate anticoagulation level at which a dental procedure can occur. Also, the administration of a "bridging agent" such as enoxaparin in preparation for the planned dental procedure reduces post-operative bleeding concerns while minimizing embolic complications.

Patients undergoing chemotherapy and/or hematopoietic stem cell transplantation are also at risk for intra-oral bleeding. They can experience spontaneous oral hemorrhage, particularly when the platelet count is less than 20,000/μL. Typically, platelet counts greater than 75,000/μL do not require additional measures for dental procedures, while lower levels require pre- and postoperative platelet transfusions.

ORTHODONTIC REFERRAL

A child's dentist usually initiates the referral to an orthodontist. For any child with a cleft palate or other craniofacial growth disorder, referral is indicated when maxillary permanent incisors are starting to erupt to prepare for an alveolar bone graft. Other localized problems such as anterior and/or posterior cross-bites and disturbances associated with the eruption of maxillary and mandibular front teeth should be addressed early to restore proper function and normal craniofacial growth. Significant arch length deficiency resulting in severe crowding requires early decisions on how to guide the developing dentition through extractions of multiple primary and permanent teeth (i.e., serial extraction sequence). Likewise, pronounced discrepancies in anterior-posterior skeletal jaw relationships warrant early evaluation by an orthodontist.
Infections of the Ear

1. Acute Otitis Externa

**Essentials of Diagnosis & Typical Features**

- **Rapid onset of symptoms within the past 3 weeks.**
- **Symptoms** of ear canal inflammation, including otalgia, itching, or fullness, with or without hearing loss or jaw pain.
- **Signs** of ear canal inflammation, including tenderness of the tragus and/or pinna, ear canal edema and/or erythema, otorrhea, regional lymphadenitis, tympanic membrane (TM) erythema, or cellulitis of the pinna and adjacent skin.

**Clinical Findings**

Symptoms include acute onset of pain, aural fullness, decreased hearing, and sometimes itching in the ear. Symptoms tend to peak within 3 days. Manipulation of the pinna or tragus causes considerable pain. Discharge may start out as clear then become purulent and may also cause secondary eczema of the auricle. The ear canal is typically swollen and narrowed, and the patient may resist any attempt to insert an otoscope. Debris is present in the canal, and it is usually very difficult to visualize the TM due to canal edema. However, it is important to determine the status of the eardrum because if there is a perforation, this is likely the cause of inflammation in the canal and may need to be managed differently, as an acute otitis media (AOM).

**Complications**

If untreated, cellulitis of the neck and face may result. Immuno-compromised individuals can develop malignant OE, which is a spread of the infection to the skull base with resultant osteomyelitis. This is a life-threatening condition and should be evaluated with a fine-cut temporal bone computed tomography (CT) scan.

**Treatment**

Management of OE includes pain control, removal of debris from the canal, topical antimicrobial therapy, and
avoidance of causative factors. Cultures are not routinely sent on the initial presentation as most cases of OE will resolve with these primary interventions. Fluoroquinolone eardrops are first-line therapy for OE. In the absence of systemic symptoms, children with OE should be treated with antibiotic eardrops only. The topical therapy chosen must be nontoxic because a perforation or patent tube may be present; if the TM cannot be visualized, then a perforation should be presumed to exist. If the ear canal is too edematous to allow entry of the eardrops, a Pope ear wick (expandable sponge) should be placed to ensure antibiotic delivery. Oral antibiotics are indicated for any signs of invasive infection, such as fever, cellulitis of the face or auricle, or tender periauricular or cervical lymphadenopathy. In such cases, in addition to the ototopical therapy, cultures of the ear canal discharge should be sent, and an antistaphylococcal antibiotic prescribed while awaiting culture results. The ear should be kept dry until the infection has cleared. If drainage persists despite therapy, cultures should be sent. Patients can have difficulty applying drops to the affected ear canal, which may cause prolonged symptoms and treatment failures. If this is suspected, thoroughly explain and demonstrate the application of the topical therapy as outlined in the Clinical Practice Guideline on Acute Otitis Externa.

2. Acute Otitis Media

AOM is the most common reason antibiotics are prescribed for children in the United States. It is an acute infection of the middle ear space associated with inflammation, effusion, or, if a patent tympanostomy tube or perforation is present, otorrhea (ear drainage).

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Moderate to severe bulging of the TM or new otorrhea not associated with OE.
- Mild bulging of the TM and less than 48 hours of otalgia (ear-holding, tugging, or rubbing in a nonverbal child) or intense erythema of the TM.
- Middle ear effusion (MEE), proven by pneumatic otoscopy or tympanometry, must be present.

**Differential Diagnosis**

Otitis media with effusion, bullous myringitis, acute mastoiditis, and middle ear mass.

**Clinical Findings**

Two findings are critical in establishing a diagnosis of AOM: a bulging TM and a MEE. The presence of MEE is best determined by visual examination and either pneumatic otoscopy or tympanometry (Figure 18–1). In order

---

**Figure 18–1.** Tympanic membrane.
to distinguish AOM from OME, signs and symptoms of middle ear inflammation and acute infection must be present. Otoscopic findings specific for AOM include a bulging TM, impaired visibility of ossicular landmarks, yellow or white effusion (pus), an opacified and inflamed eardrum, and sometimes squamous exudate or bullae on the eardrum.

A. Pathophysiology and Predisposing Factors

1. Eustachian tube dysfunction (ETD)—The Eustachian tube regulates middle ear pressure and allows for drainage of the middle ear. The ciliated respiratory epithelium of the Eustachian tube also defends against pathogens by producing lysozyme and mucus, which helps rid the ear of microorganisms. It must periodically open to prevent the development of negative pressure and effusion in the middle ear space. If this does not occur, negative pressure leads to transudation of cellular fluid into the middle ear, as well as influx of fluids and pathogens from the nasopharynx and adenoids. Middle ear fluid may then become infected, resulting in AOM. The Eustachian tube of infants and young children is more prone to dysfunction because it is shorter, more compliant, and more horizontal than in adults. The Eustachian tube reaches its adult configuration by the age of 7 years. Infants with craniofacial disorders, such as Down syndrome or cleft palate, may be particularly susceptible to ETD.

2. Bacterial colonization— Nasopharyngeal colonization with *S. pneumoniae*, *Haemophilus influenzae*, or *Moraxella catarrhalis* increases the risk of AOM, whereas colonization with normal flora such as viridans streptococci may prevent AOM by inhibiting growth of these pathogens.

3. Viral upper respiratory infections—Upper respiratory infections (URIs) impair Eustachian tube function by causing adenoid hypertrophy and edema of the Eustachian tube itself. Viral infections also inhibit the antibacterial properties of mucus and mucociliary clearance. It is not absolutely clear if viral pathogens are the primary cause of episodes of AOM or if they help promote bacterial infections.

4. Smoke exposure—Passive smoking increases the risk of persistent MEE by enhancing colonization, prolonging the inflammatory response, and impeding drainage of the middle ear through the Eustachian tube. For infants aged 12–18 months, cigarette exposure is associated with an 11% per pack increase in the duration of MEE.

5. Impaired host immune defenses—Immunocompromised children such as those with selective IgA deficiency usually experience recurrent AOM, rhinosinusitis, and pneumonia. However, most children who experience recurrent or persistent otitis only have selective impairments of immune defenses against specific otitis pathogens.

6. Bottle feeding—Breast-feeding reduces the incidence of acute respiratory infections, provides immunoglobulin A (IgA) antibodies that reduce colonization with otitis pathogens, and decreases the aspiration of contaminated secretions into the middle ear space, which can occur when a bottle is propped in the crib.

7. Season—The incidence of AOM correlates with the activity of respiratory viruses, accounting for the annual surge in otitis media cases during the winter months in temperate climates.

8. Day care attendance—Children exposed to large groups of children have more respiratory infections and OM. The increased number of children in day care over the past three decades has undoubtedly played a major role in the increase in AOM in the United States.

9. Genetic susceptibility—Genes are thought to play a role in 40%–70% of ear infections. Most of the genes responsible regulate immunity. However, environmental and pathogen-related causes also play a role. Further research is being conducted to further characterize the role of genetics in AOM.

10. Age—Children ages 1–3 years are at greatest risk for AOM.

B. Microbiology of Acute Otitis Media

Bacterial or viral pathogens can be detected in up to 96% of middle ear fluid samples from patients with AOM. Polymicrobial infections are seen in up to 55% of cases, with bacterial and viral coinfections occurring in up to 70%.

- *S. pneumoniae* and *H. influenzae* account for 35%–40% and 30%–35% of isolates, respectively. With widespread use of the pneumococcal conjugate vaccine starting in 2000, the incidence of AOM caused by *H. influenzae* rose while that of the *S. pneumoniae* vaccine serotypes declined. However, there has been an increase in disease caused by *S. pneumoniae* serotypes not covered by the vaccine as well as *S. aureus*. The third most common pathogen cited is *M. catarrhalis*, which causes up to 15%–25% of AOM cases in the United States (Table 18–1). The fourth most common organism in AOM is *Streptococcus pyogenes*, which is found more frequently in school-aged children than in infants.

S pneumoniae and S pyogenes are the predominant causes of mastoiditis. The most common viruses associated with AOM are RSV, influenza virus, adenovirus, human meta-pneumovirus, and enteroviruses.

Drug-resistant S pneumoniae is a common pathogen in AOM and strains may be resistant to only one drug class (eg, penicillins or macrolides) or to multiple classes. Children with resistant strains tend to be younger and to have had more unresponsive infections. Antibiotic treatment in the preceding 3 months also increases the risk of harboring resistant pathogens.

C. Examination Techniques and Procedures

1. Pneumatic otoscopy—AOM is overdiagnosed, leading to inappropriate antibiotic therapy, unnecessary surgical referrals, and significant associated costs. Contributing to errors in diagnosis is the temptation to accept the diagnosis without removing enough cerumen to adequately visualize the TM, and the mistaken belief that a red TM establishes the diagnosis. Redness of the TM is often a vascular flush caused by fever or crying.

A pneumatic otoscope with a rubber suction bulb and tube is used to assess TM mobility. When used correctly, pneumatic otoscopy can improve diagnostic ability by 15%–25%. The largest possible speculum should be used to provide an airtight seal and maximize the field of view. When the rubber bulb is gently squeezed, the TM should move freely with a snapping motion; if fluid is present in the middle ear space, the mobility of the TM will be absent or resemble a fluid wave. The ability to assess mobility is compromised by failure to achieve an adequate seal with the otoscope, poor visualization due to low light intensity, and mistaking the ear canal wall for the membrane.

2. Cerumen removal—Cerumen (ear wax) removal is an essential skill for anyone who cares for children. Impacted cerumen pushed against the TM can cause itching, pain, or hearing loss. Parents should be advised that cerumen actually protects the ear and usually comes out by itself through the natural sloughing and migration of the skin of the ear canal. Parents should never put anything into the ear canal to remove wax.

Cerumen may be safely removed under direct visualization through the operating head of an otoscope, provided two adults are present to hold the child. A size 0 plastic disposable ear curette may be used. Irrigation can also be used to remove hard or flaky cerumen. Wax can be softened with 1% sodium docusate solution, carbamyl peroxide solutions, or mineral oil before irrigation is attempted. A perforated TM or patent tympanostomy tube is a contraindication to any form of irrigation.

A home remedy for recurrent cerumen impaction is placing a few drops of oil such as mineral or olive oil in the EAC a couple of times a week, warmed to body temperature to prevent dizziness.

3. Tympanometry—Tympanometry can be helpful in assessing middle ear status, particularly when pneumatic otoscopy is inconclusive or difficult to perform. Tympanometry can reveal the presence or absence of a MEE but cannot differentiate between acutely infected fluid (AOM) and a chronic effusion (OME).

Tympanometry measures TM compliance and displays it in graphic form. It also measures the volume of the ear canal, which can help differentiate between an intact and perforated TM.

Standard 226-Hz tympanometry is not reliable in infants younger than 6 months. A high-frequency (1000 Hz) probe is used in this age group.

Tympanograms can be classified into four major patterns, as shown in Figure 18–2. The pattern shown in Figure 18–2A, characterized by maximum compliance at normal atmospheric pressure, indicates a normal TM, good Eustachian tube function, and absence of effusion. Figure 18–2B identifies a nonmobile TM with normal volume, which indicates MEE. Figure 18–2C indicates an intact, mobile TM with excessively negative middle ear pressure (> –150 daPa), indicative of poor Eustachian tube function. Figure 18–2D shows a flat tracing with a large middle ear volume, indicative of a patent tube or TM perforation.

Treatment

A. Pain Management

Pain is the primary symptom of AOM, and the 2013 clinical practice guidelines emphasize the importance of addressing this symptom. As it may take 1–3 days before antibiotic therapy leads to a reduction in pain, mild to moderate pain should be treated with ibuprofen or acetaminophen. Severe pain should be treated with narcotics, but careful and close observation is required to address possible respiratory depression, altered mental status, gastrointestinal upset, and constipation. Topical analgesics have a very short duration and studies do not support efficacy in children younger than 5 years.

B. The Observation Option

The choice to observe an episode of AOM and not treat with antibiotics is an option in otherwise healthy children without other underlying conditions such as cleft palate, craniofacial abnormalities, immune deficiencies, cochlear implants, or tympanostomy tubes. The decision should be made in conjunction with the parents, and a mechanism must be in place to provide antibiotic therapy if there is worsening of symptoms or lack of improvement within 48–72 hours. For infants younger than 6 months, antibiotics are always recommended on the first visit, regardless of diagnostic certainty. The 2013 clinical practice guidelines include age, presence of otorrhea, severity of symptoms, and laterality as criteria for antibiotic treatment versus observation (Table 18–2).
**Figure 18–2.** Four types of tympanograms obtained with Welch-Allyn MicroTymp 2. A: Normal middle ear. B: Otitis media with effusion or AOM. C: Negative middle ear pressure due to ETD. D: Patent tympanostomy tube or perforation in the TM. Same as B except for a very large middle ear volume.

\(^b\)A toxic-appearing child, persistent otalgia for more than 48 hours, temperature > 39°C (102.2°F) in the past 48 hours, or if there is uncertain access to follow-up after the visit.

This plan of initial management provides an opportunity for shared decision-making with the child’s family for those categories appropriate for initial observation. If observation is offered, a mechanism must be in place to ensure follow-up and begin antibiotics if the child worsens or fails to improve within 48–72 hours of AOM onset.
C. Antibiotic Therapy

High-dose amoxicillin remains the first-line antibiotic for treating AOM, even with a high prevalence of drug-resistant *S pneumoniae*, because data show that isolates of the bacteria remain susceptible to the drug 83%–87% of the time.

Amoxicillin-clavulanate enhanced strength (ES), with 90 mg/kg/d of amoxicillin dosing (14:1 ratio of amoxicillin:clavulanate), is an appropriate choice when a child has had amoxicillin in the last 30 days, or is clinically failing after 48–72 hours on amoxicillin (Table 18–3) or has concomitant conjunctivitis. Purulent conjunctivitis is often caused by non-typeable *H influenzae*. The regular strength formulations of amoxicillin-clavulanate (7:1 ratio) should not be doubled in dosage to achieve 90 mg/kg/d of amoxicillin, because the increased amount of clavulanate will cause diarrhea.

Three oral cephalosporins (cefuroxime, cefpodoxime, and cefdinir) are more β-lactamase–stable and are alternative choices in children who develop a papular rash with amoxicillin (see Table 18–3). Unfortunately, coverage of highly penicillin-resistant pneumococci with these agents is poor and only the intermediate-resistance classes are covered. Of these drugs, cefdinir suspension is most palatable; the other two have a bitter after-taste which is difficult to conceal. Flavoring agents may be helpful here.

A second-line antibiotic is indicated when a child experiences symptomatic infection within 1 month of finishing amoxicillin; however, repeated use of high-dose amoxicillin is indicated if more than 4 weeks have passed without symptoms. Macrolides such as azithromycin and clarithromycin are not recommended as second-line agents because *S pneumoniae* is resistant to macrolides in approximately 30% of respiratory isolates, and because virtually all strains of *H influenzae* have an intrinsic macrolide efflux pump, which pumps the antibiotic out of the bacterial cell. However, if there is a history of type 1 hypersensitivity reaction, macrolides may be used.

Reasons for failure to eradicate a sensitive pathogen include drug noncompliance, poor drug absorption, or vomiting of the drug. If a child remains symptomatic for longer than 3 days while taking a second-line agent, a tympanocentesis is useful to identify the causative pathogen. If a highly resistant pneumococcus is found or if tympanocentesis is not feasible, intramuscular ceftriaxone at 50 mg/kg/dose for

3 consecutive days is recommended. If a child has experienced a severe reaction, such as anaphylaxis, to amoxicillin, cephalosporins should not be substituted. Otherwise, the risk of cross-sensitivity is less than 0.1%. Multidrug-resistant *S. pneumoniae* poses a treatment dilemma and newer antibiotics, such as fluoroquinolones or linezolid, may need to be employed. However, these drugs are not approved by the U.S. Food and Drug Administration (FDA) for the treatment of AOM in children.

In patients with tympanostomy tubes with uncomplicated acute otorhea, ototopical antibiotics (fluoroquinolone eardrops) are first-line therapy. The eardrops serve two purposes: (1) They treat the infection and (2) they physically "rinse" drainage from the tube which helps prevent plugging of the tube. Oral antibiotics are not indicated in the absence of systemic symptoms.

If a TM perforation has occurred with otorhea then topical antibiotics are recommended as first-line agents due to the ability to provide high concentrations of antibiotic directly to the middle ear. Topical fluoroquinolone otic drops (ofloxacin and ciprofloxacin) with or without steroids are considered safe for administration into the middle ear. If there is a large amount of debris or drainage in the ear canal, the canal may need to be suctioned first in order for the drops to gain access to the middle ear.

**D. Tympanocentesis**

Tympanocentesis is performed by placing a needle through the TM and aspirating the middle ear fluid. The fluid is sent for culture and sensitivity. Indications for tympanocentesis are (1) AOM in an immunocompromised patient, (2) research studies, (3) evaluation for presumed sepsis or meningitis, such as in a neonate, (4) unresponsive otitis media despite courses of two appropriate antibiotics, and (5) acute mastoiditis or other suppurative complications. Tympanocentesis can be performed with an open-headed operating otoscope or a binocular microscope with either a spinal needle and 3-mL syringe, or if available, an Alden-Senturia trap (Storz Instrument Co., St. Louis, MO) or the Tym-Tap aspirator (Xomed Surgical Products, Jackson, FL) (Figure 18–3).

**E. Prevention of Acute Otitis Media**

1. **Antibiotic prophylaxis**—Strongly discouraged. Antibiotic resistance is a concern and studies have shown poor efficacy.

2. **Lifestyle modifications**—Parental education plays a major role in decreasing AOM.
   - Smoking is a risk factor both for URI and AOM. Primary care physicians should provide information on smoking cessation programs and measures.

• Breast-feeding protects children from AOM. Clinicians should encourage exclusive breast-feeding for 6 months.

• Bottle-propping in the crib should be avoided. It increases AOM risk due to the reflux of milk into the Eustachian tubes.

• Pacifiers are controversial. In Finland, removing pacifiers from infants was shown to reduce AOM episodes by about one-third compared to a control group. The mechanism is uncertain but likely to be related to effects on the Eustachian tube. However, the benefit of pacifier use in reducing sudden infant death syndrome-related deaths is also important to consider. Currently, the recommendation from the American Academy of Family Physicians is to wean a pacifier if used after 6 months of age to reduce the risk of AOM.

• Day care is a risk factor for AOM, but working parents may have few alternatives. Possible alternatives include care by relatives or child care in a setting with fewer children.

3. **Surgery**—Tympanostomy tubes are effective in the treatment of recurrent AOM as well as OME.
4. Immunologic evaluation and allergy testing—While immunoglobulin subclass deficiencies may be more common in children with recurrent AOM, there is no practical immune therapy available. More serious immunodeficiencies, such as selective IgA deficiency, should be considered in children who suffer from a combination of recurrent AOM, rhinosinusitis, and pneumonia. In the school-aged child or preschooler with an atopic background, skin testing may be beneficial in identifying allergens that can predispose to AOM.

5. Vaccines—The pneumococcal conjugate and influenza vaccines are recommended. The seven-valent pneumococcal conjugate vaccine (PCV7) was introduced in the United States in 2000, and the 13-valent pneumococcal conjugate vaccine (PCV13) in 2010. PCV7 was found to produce a 29% reduction in AOM resulting from the seven serotypes found in the vaccine, and overall, PCV7 reduced AOM by 6%–7%, according to a 2009 Cochrane database review. Data are not yet available regarding the effect of PCV13 on AOM at this time. In recent studies, intranasal influenza vaccine reduced the number of influenza-associated cases of AOM by 30%–55%.

Web Resources
http://www.entnet.org/content/patient-health

3. Otitis Media With Effusion

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▷ MEE with decreased TM mobility as diagnosed on pneumatic otoscopy.
▷ No signs or symptoms of acute inflammation.
▷ OME should not be treated with antibiotics.

Clinical Findings
Otitis media with effusion (OME) is the presence of fluid in the middle ear space without signs or symptoms of acute inflammation. This is relatively common with 90% of children having one episode of OME by age 5. Children may have mild discomfort, but acute pain, fever or erythema of the ear canal or the TM are not characteristic. On examination, the TM may be opacified and thickened and the middle ear fluid can be clear, amber-colored, or opaque. Pneumatic otoscopy should be performed to confirm the presence of a MEE. If the pneumatic otoscopy examination is uncertain, then tympanometry should be performed to confirm presence of middle ear fluid.

Children with OME can develop AOM if the middle ear fluid should become infected. After AOM, fluid can remain in the ear for several weeks, with 60%–70% of children still having MEE 2 weeks after successful treatment. This drops to 40% at 1 month and 10%–25% at 3 months after treatment. It is important to distinguish OME from AOM because the former does not benefit from treatment with antibiotics.

Management
An audiology evaluation should be performed after approximately 3 months of continuous bilateral effusion in most children. However, children who are at risk of language delay due to socioeconomic circumstances, craniofacial anomalies, or other risk factors should undergo a hearing evaluation at the time that OME is diagnosed. Children with hearing loss or speech delay should be referred to an otolaryngologist for possible tympanostomy tube placement. Antibiotics, antihistamines, and steroids have not been shown to be useful in the treatment of OME.

In uncomplicated cases, OME is observed for 3 months prior to consideration for tympanostomy tube placement. Longer periods of observation may be acceptable in children with normal or very mild hearing loss on audiogram, no risk factors for speech and language issues, and no structural changes to the TM. These children should be followed every 3–6 months until the effusions clear or complications develop. Indications for tympanostomy tubes include hearing loss greater than 40 dB, TM retraction pockets, ossicular erosion, adhesive atelectasis, and cholesteatoma. In children older than age 4, adenoidectomy may be recommended with ear tubes as studies show this can reduce failure rate and need for additional surgeries.

Prognosis & Sequelae
Prognosis is variable based on age of presentation. Infants who are very young at the time of first otitis media are more likely to need surgical intervention. Other factors that decrease the likelihood of resolution are onset of OME in the summer or fall, history of prior tympanostomy tubes, presence of adenoids, and hearing loss greater than 30 dB.
Complications of Otitis Media

A. Tympanosclerosis, Retraction Pockets, Adhesive Otitis

Tympanosclerosis is an acquired disorder of calcification and scarring of the TM and middle ear structures secondary to inflammation. If tympanosclerosis involves the ossicles, a conductive hearing loss may result. The term myringosclerosis applies to calcification of the TM only and is a fairly common sequela of OME and AOM. Myringosclerosis may also develop at the site of a previous tympanostomy tube; tympanosclerosis is not a common sequela of tube placement. Myringosclerosis rarely causes hearing loss, unless the entire TM is involved ("porcelain eardrum"). Myringosclerosis may be confused with a middle ear mass. However, use of pneumatic otoscopy can often help in differentiation, as the plaque will usually move with the TM during insufflation.

The appearance of a small defect or invagination of the pars tensa or pars flaccida of the TM suggests a retraction pocket. Retraction pockets occur when chronic inflammation and negative pressure in the middle ear space produce atrophy and atelectasis of the TM.

Continued inflammation can cause adhesions to form between the retracted TM and the ossicles. This condition, referred to as adhesive otitis, predisposes one to formation of a cholesteatoma or fixation and erosion of the ossicles.

B. Cholesteatoma

A greasy-looking or pearly white mass seen in a retraction pocket or perforation behind the eardrum suggests a cholesteatoma (Figure 18–4). If infection is superimposed, serous or purulent drainage will be seen, and the middle ear cavity may contain granulation tissue or even polyps. Persistent, recurrent, or foul-smelling otorrhea following appropriate medical management should make one suspect a cholesteatoma and patients should be referred to an ENT.

C. Tympanic Membrane Perforation

Occasionally, an episode of AOM may result in rupture of the TM. Discharge from the ear is seen, and often there is rapid relief of pain. Perforations due to AOM usually heal spontaneously within a couple of weeks. Ototopical antibiotics are recommended for a 10- to 14-day course and patients should be referred to an otolaryngologist 2–3 weeks after the rupture for examination and hearing evaluation.

D. Facial Nerve Paralysis

The facial nerve traverses the middle ear as it courses through the temporal bone to its exit at the stylomastoid foramen. Normally, the facial nerve is completely encased in bone, but occasionally bony dehiscence in the middle ear is present, exposing the nerve to infection and making it susceptible to inflammation during an episode of AOM. The acute onset of a facial nerve paralysis should not be deemed idiopathic Bell palsy until all other causes have been excluded. If middle ear fluid is present, prompt myringotomy and tube placement are indicated. CT is indicated if a cholesteatoma or mastoiditis is suspected.

E. Chronic Suppurative Otitis Media

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Ongoing purulent ear drainage.
- Nonintact TM: perforation or tympanostomy tubes.
- May be associated with cholesteatoma.

When perforations fail to heal, surgical repair may be needed. TM repair is generally delayed until the child is older and Eustachian tube function has improved. Repair of the eardrum (tympanoplasty) is generally deferred until around 7 years of age, which is approximately when the Eustachian tube reaches adult orientation.

In the presence of a perforation, water activities should be limited to surface swimming, preferably with the use of an ear mold.
Chronic suppurative otitis media (CSOM) is present when persistent otorrhea occurs in a child with tympanostomy tubes or TM perforation. It starts with an acute infection that becomes chronic with mucosal edema, ulceration, granulation tissue, and eventual polyp formation. Risk factors include a history of multiple episodes of otitis media, living in crowded conditions, day care attendance and being a member of a large family. The most common associated bacteria include *P aeruginosa*, *S aureus*, *Proteus* species, *Klebsiella pneumoniae*, and diphtheroids.

Visualization of the TM, meticulous cleaning with culture of the drainage, and appropriate antimicrobial therapy, usually topical, are the keys to management.

Occasionally, CSOM may be a sign of cholesteatoma or other disease process such as foreign body, neoplasm, Langerhans cell histiocytosis, tuberculosis, granulomatosis, fungal infection, or petrositis. If CSOM is not responsive to culture-directed treatment, imaging and biopsy may be needed to rule out other possibilities. Patients with facial palsy, vertigo, or other CNS signs should be referred immediately to an otolaryngologist.

**F. Labyrinthitis**

Suppurative infections of the middle ear can spread into the membranous labyrinth of the inner ear. Symptoms include vertigo, hearing loss, and fevers. The child often appears extremely toxic. Intravenous antibiotic therapy is used, and intravenous steroids may also be used to help decrease inflammation. Sequelae can be serious, including a condition known as *labyrinthitis ossificans*, or bony obliteration of the inner ear, including the cochlea, leading to profound hearing loss.

**G. Mastoiditis**

**Pathogenesis**

Mastoiditis occurs when infection spreads from the middle ear space to the mastoid portion of the temporal bone, which lies just behind the ear and contains air-filled spaces. Mastoiditis can range in severity from inflammation of the mastoid periosteum to bony destruction of the mastoid air cells (coalescent mastoiditis) with abscess development. Mastoiditis can occur in any age group, but more than 60% of the patients are younger than 2 years. Many children do not have a prior history of recurrent AOM.

**Clinical Findings**

**A. Symptoms and Signs**

Patients with mastoiditis usually have postauricular pain, fever, and an outwardly displaced pinna. On examination, the mastoid area often appears indurated and red and with disease progression, it may become swollen and fluctuant. The earliest finding is severe tenderness on mastoid palpation. AOM is almost always present. Late findings include a pinna that is pushed forward by postauricular swelling and an ear canal that is narrowed due to pressure on the postero-superior wall from the mastoid abscess. In infants younger than 1 year, the swelling occurs superior to the ear and pushes the pinna downward rather than outward.

**B. Imaging Studies**

The best way to determine the extent of disease is by CT scan. Early mastoiditis is radiographically indistinguishable from AOM, with both showing opacification but no destruction of the mastoid air cells. With progression of mastoiditis, coalescence of the mastoid air cells is seen with bone destruction.

**C. Microbiology**

The most common pathogens are *S pneumoniae* followed by *H influenzae* and *S pyogenes*. Rarely, gram-negative bacilli and anaerobes are isolated. Antibiotics may decrease the incidence and morbidity of acute mastoiditis. However, acute mastoiditis still occurs in children who are treated with antibiotics for an acute ear infection. In the Netherlands, where only 31% of AOM patients receive antibiotics, the incidence of acute mastoiditis is 4.2 per 100,000 person-years. In the United States, where more than 96% of patients with AOM receive antibiotics, the incidence of acute mastoiditis is 2 per 100,000 person-years. Despite the routine use of antibiotics, the incidence of acute mastoiditis has been rising in some cities. The pattern change may be secondary to the emergence of resistant *S pneumoniae*.

**Differential Diagnosis**

Lymphadenitis, parotitis, trauma, tumor, histiocytosis, OE, and furuncle.
Complications

Meningitis can be a complication of acute mastoiditis and should be suspected when a child has associated high fever, stiff neck, severe headache, or other meningeal signs. Lumbar puncture should be performed for diagnosis. Brain abscess occurs in 2% of mastoiditis patients and may be associated with persistent headaches, recurring fever, or changes in sensorium. Facial palsy, sigmoid sinus thrombosis, epidural abscess, cavernous sinus thrombosis, and thrombophlebitis may also be encountered.

Treatment

In the preantibiotic era, up to 20% of patients with AOM developed mastoiditis requiring mastoidectomy. Now, the occurrence is 5 cases per 100,000 persons with AOM. Intravenous antibiotic treatment alone may be successful if there is no evidence of coalescence or abscess on CT. However, if there is no improvement within 24–48 hours, surgical intervention should be undertaken. Minimal surgical management starts with tympanostomy tube insertion, during which cultures are taken. If a subperiosteal abscess is present, incision and drainage is also performed, with or without a cortical mastoidectomy. Intracranial extension requires complete mastoidectomy with decompression of the involved area.

Antibiotic therapy (intravenous and topical ear drops) is instituted along with surgical management and relies on culture-directed antibiotic therapy for 2–3 weeks. An antibiotic regimen should be chosen which is able to cross the blood-brain barrier. After significant clinical improvement is achieved with parenteral therapy, oral antibiotics are begun and should be continued for 2–3 weeks. A patent tympanostomy tube must also be maintained with continued use of otic drops until drainage abates.

Prognosis

Prognosis for full recovery is good. Children that develop acute mastoiditis with abscess as their first ear infection are not necessarily prone to recurrent otitis media.

EAL CANAL FOREIGN BODY & CERUMEN IMPACTION

Foreign bodies of the ear canal, both intentional (placement by patient or other person) or accidental (e.g., insect, playground mulch), are common in childhood. Cerumen can also be obstructive, acting like a foreign body. These objects can be removed if they are easy to visualize and there is appropriate instrumentation. Factors that may make them difficult to remove include size of foreign body, particularly when large enough to obscure the TM, rounded or globular objects, and objects deep in the ear canal adjacent to the TM. If these conditions exist or you are unable to remove the object on the first attempt, an ENT referral is often necessary for resolution. Vegetable matter should never be irrigated for resolution. Blood collecting in the middle ear space may cause a conductive hearing loss that will resolve with time. Antibiotics are not necessary unless signs of infection appear. The patient needs to be followed with audiometry or by an otolaryngologist until hearing has returned to normal, which is expected within 6–8 weeks. If the conductive hearing loss does not resolve, there may be injuries to the ossicular chain. A CT scan may be needed to evaluate the middle ear structures in this case.

Traumatic TM perforations should be referred to an otolaryngologist for examination and hearing evaluation. Spontaneous healing may occur within 6 months of the perforation. In the acute setting, antibiotic ear drops are often recommended to provide a moist environment which is thought to speed healing.
from irritation. Education on the proper techniques of ear cleaning (such as only cleaning the external meatus) is important to avoid impactions. Explaining to parents that cerumen production is normal and cerumen actually protects the ear canal skin can help reinforce proper ear care.

AURICULAR HEMATOMA

Trauma to the outer ear can result in formation of a hematoma between the perichondrium and cartilage of the pinna. This is different from a bruise, which does not change the ear shape and where the blood is in the soft tissue outside of the perichondrial layer. A hematoma appears as a boggy purple swelling of the cartilaginous auricle, and the normal folds of the ear are obscured. If untreated, necrosis of the underlying cartilage may occur, resulting in “cauliflower ear.” To prevent this cosmetic deformity, physicians should urgently refer patients to an otolaryngologist for drainage and application of a pressure dressing. Antibiotics that cover *Pseudomonas spp.* are also recommended.

CONGENITAL EAR MALFORMATIONS

**Atresia** is failure of the ear canal to form. This results in conductive hearing loss and should be evaluated within the first 3 months of life by an audiologist and otolaryngologist.

**Microtia** is the term used for an external ear that is small, collapsed, or only has an earlobe present. **Anotia** refers to an absent external ear. Often, there is an associated atresia with microtia and anotia. Reconstruction can be performed in girls around age 6 and in boys around age 8–10 years.

“Lop ears,” folded down, or protruding ears (“Dumbo ears”) can be a source of much teasing and ridicule. Taping of the ears into correct anatomic position is very effective if performed in the first 72–96 hours of life. Tape is applied over a molding of wax or plastic and continued for at least 2 weeks. If this window of opportunity is missed or taping is unsuccessful, surgical correction, called an “otoplasty,” can be performed later.

An ear is considered “low-set” if the upper pole is below eyebrow level. This condition is often associated with other congenital anomalies, and in these patients a genetics evaluation should be considered.

Preauricular tags, ectopic cartilage, fistulas, and cysts require surgical correction primarily for cosmetic reasons. Children exhibiting any of these findings should have their hearing tested. Renal ultrasound should be considered, as external ear anomalies can be associated with renal anomalies, as both structures form during the same period of embryogenesis. Most preauricular pits cause no symptoms but can become infected. If one should become infected, the patient should receive antibiotic therapy and be referred to an otolaryngologist for possible excision.

**IDENTIFICATION & MANAGEMENT OF HEARING LOSS**

Hearing loss is classified as being conductive, sensorineural, or mixed in nature. Conductive hearing loss occurs when sound transmission is blocked somewhere between the opening of the external ear and the cochlear receptor cells. The most common cause of conductive hearing loss in children is fluid in the middle ear. Sensorineural hearing loss is due to a defect in the neural transmission of sound, arising from a defect in the cochlear hair cells or the auditory nerve. Mixed hearing loss is characterized by elements of both conductive and sensorineural loss.

Hearing is measured in decibels (dB). The threshold, or 0 dB, refers to the level at which a sound is perceived in normal subjects 50% of the time. Hearing is considered normal if an individual’s thresholds are within 20 dB of normal. In children, severity of hearing loss is commonly graded as follows: 20–40 dB mild, 41–55 dB moderate, 56–70 dB moderately severe, 71–90 dB severe, and 91+ dB profound.

Hearing loss can significantly impair a child’s ability to communicate and hinder academic, social, and emotional development. Studies suggest that periods of auditory deprivation may have enduring effects on auditory processing, even after normal hearing is restored. Even a unilateral loss may be associated with difficulties in school and behavioral issues. Early identification and management of any hearing loss is therefore critical.

**Conductive Hearing Loss**

The most common cause of childhood conductive hearing loss is otitis media and related conditions such as MEE and ETD. Other causes may include external auditory canal...
ated with nonsyndromic hearing loss is in the genetic problems. The most common known mutation associ-
ated with nonsyndromic hearing loss include the following: Waardenburg, branchio-oto-renal, Jervell and Lange-Nielsen, and Alport.

Over 70% of hereditary hearing loss is nonsyndromic (ie, there are no associated visible abnormalities or related medical problems). The most common known mutation associated with nonsyndromic hearing loss is in the GJB2 gene, which encodes the protein Connexin 26. The GJB2 mutation has a carrier rate of about 3% in the general population. Most nonsyndromic hearing loss, including that due to the GJB2 mutation, is autosomal recessive.

B. Acquired Hearing Loss

Hereditary hearing loss may be delayed in onset, as in Alport syndrome and most types of autosomal dominant non-
syndromic hearing loss. Vulnerability to aminoglycoside-induced hearing loss has also been linked to a mitochondrial gene defect.

Nongenetic etiologies for delayed-onset SNHL include exposure to ototoxic medications, meningitis, autoimmune or neoplastic conditions, noise exposure, and trauma. Infections such as syphilis or Lyme disease have been associated with hearing impairment. Hearing loss associated with congenital cytomegalovirus (CMV) infection may be present at birth, or may have a delayed onset. The loss is progressive in approximately half of all patients with congenital CMV-associated hearing loss. Other risk factors for delayed-onset, progressive loss include a history of persistent pulmonary hypertension and extracorporeal membrane oxygenation therapy.

Identification of Hearing Loss

A. Newborn Hearing Screening

Prior to the institution of universal newborn screening pro-
grams, the average age at identification of hearing loss was 30 months. Recognizing the importance of early detection, in 1993, a National Institutes of Health Consensus Panel recommended that all newborns be screened for hearing impairment prior to hospital discharge. Today, all 50 states and the District of Columbia have Early Hearing Detection and Intervention (EHDI) laws or screening programs, and as of 2014, 97% of newborns in the United States were screened for hearing loss. The EHDI goal is loss identification and confirmation of hearing loss by 3 months of age, and appropriate intervention by the age of 6 months. Updated recommendations in the future are expected to lower the age recommendations for confirmed diagnosis and intervention. Subjective testing is not reliable in infants, and therefore objective, physiologic methods are used for screening. Auditory brainstem response and otoacoustic emission testing are the two commonly employed screening modalities.

B. Audiologic Evaluation of Infants and Children

A parent’s report of his or her infant’s behavior cannot be relied upon for identification of hearing loss. A deaf infant’s behavior can appear normal and mislead parents and professionals. Deaf infants are often visually alert and able to actively scan the environment which may be
Conventional audiometry (5 years and up): The child
conditioned play audiometry (2.5–5 years): The child
avoiding a missed diagnosis.

Even if a newborn screening was passed, all infants who fall
in children with a history of in utero CMV
exposure, should be referred for regular audiologic monitor-
ing for the first 3 years and at appropriate intervals thereafter
in children with a history of developmental delay, bacte-
ries for SNHL as outlined earlier, hearing should be tested
in children with a history of infection such as mumps
management. Prompt and appropriate intervention
can be corrected. For example, hearing loss due
to chronic effusions usually normalizes once the fluid has
cleared, whether by natural means or by the placement of
tympanostomy tubes. As of yet, SNHL is not reversible.
Most sensorineural loss is managed with amplification.
Cochlear implantation is an option for some children with
severe-profound loss, and is FDA approved down to the
age of 12 months. Unlike hearing aids, cochlear implants
do not amplify sound, but directly stimulate the cochlea with
electrical impulses.

When a hearing loss is diagnosed, it is not known
whether it will remain stable, or if it will fluctuate or worsen.
Therefore, children with hearing loss should receive ongoing
audiologic monitoring, as well as periodic assessments of
global development and functional performance.

The Individuals with Disabilities Education Act 2004
(IDEA 2004) is a United States law mandating free access
to individualized educational opportunities with qualified
instructors for children with disabilities, including hearing
loss. Part C provides early intervention for children up to
age 3 years. Audiologists play an important role in the transi-
tion from diagnosis to intervention, as they are required
to initiate a referral to their state’s Part C program within
7 days of a new confirmed permanent hearing loss diagno-
sis. Each child who is referred undergoes assessment by a
team of experts and an Individualized Family Service Plan is
developed. The ISFP may enlist the services of audiologists,
speech-language pathologists, and other related profession-
als as warranted. The IFSP is family-centered, and family
support services are often available. Between the ages of
3–21 years, children are covered under Part B of IDEA 2004.
Part B is managed through the local school systems’ special
education programs. Under Part B, an Individualized Edu-
cation Plan (IEP) is developed with a goal of maximizing a
child’s academic success.

Management of Hearing Loss

While identification of hearing loss is the critical first step,
it is largely meaningless without appropriate follow-up
and management. Prompt and appropriate intervention
can minimize the potential lifelong detrimental effects that
hearing loss can have on language, academic, emotional and
social development, and hearing-related quality of life. The
optimal management of pediatric hearing loss requires a
multidisciplinary approach. The team may include audiolo-
gists, otolaryngologists, speech-language pathologists, early
intervention specialists, deaf-hard of hearing educational
specialists and family counselors.

Any child with confirmed hearing loss should be referred
to an otolaryngologist for further evaluation and possible
medical and/or surgical management. Etiologic workup
include radiographic imaging and/or laboratory tests
and should be tailored to each individual patient’s history,
examination, and audiometric results. Within the past
several years, major advances have made comprehensive
genetic testing for syndromic and nonsyndromic hearing
loss using next-generation sequencing technology available
to the public.

The medical management of hearing loss depends upon
the type and severity. Conductive hearing loss is sometimes
fixable if the point at which sound transmission is com-
promised can be corrected. For example, hearing loss due
to chronic effusions usually normalizes once the fluid has
bled, whether by natural means or by the placement of
tympanostomy tubes. As of yet, SNHL is not reversible.
Most sensorineural loss is managed with amplification.
Cochlear implantation is an option for some children with
severe-profound loss, and is FDA approved down to the
age of 12 months. Unlike hearing aids, cochlear implants
do not amplify sound, but directly stimulate the cochlea with
electrical impulses.

When a hearing loss is diagnosed, it is not known
whether it will remain stable, or if it will fluctuate or worsen.
Therefore, children with hearing loss should receive ongoing
audiologic monitoring, as well as periodic assessments of
global development and functional performance.

The Individuals with Disabilities Education Act 2004
(IDEA 2004) is a United States law mandating free access
to individualized educational opportunities with qualified
instructors for children with disabilities, including hearing
loss. Part C provides early intervention for children up to
age 3 years. Audiologists play an important role in the transi-
tion from diagnosis to intervention, as they are required
to initiate a referral to their state’s Part C program within
7 days of a new confirmed permanent hearing loss diagno-
sis. Each child who is referred undergoes assessment by a
team of experts and an Individualized Family Service Plan is
developed. The ISFP may enlist the services of audiologists,
speech-language pathologists, and other related profession-
als as warranted. The IFSP is family-centered, and family
support services are often available. Between the ages of
3–21 years, children are covered under Part B of IDEA 2004.
Part B is managed through the local school systems’ special
education programs. Under Part B, an Individualized Edu-
cation Plan (IEP) is developed with a goal of maximizing a
child’s academic success.
Prevention
Appropriate care may treat or prevent certain conditions causing hearing deficits. Aminoglycosides and diuretics, particularly in combination, are potentially ototoxic and should be used judiciously and monitored carefully. Given the association of a mitochondrial gene defect with aminoglycoside ototoxicity, use should be avoided when possible, in patients with a family history of aminoglycoside-related hearing loss. Reduction of repeated exposure to loud noises may prevent high-frequency hearing loss associated with acoustic trauma. Any patient with sudden-onset SNHL should be seen by an otolaryngologist immediately, as in some cases, steroid therapy may reverse the loss if initiated right away.

CHAPTER 18

THE NOSE & PARANASAL SINUSES

ACUTE VIRAL RHINITIS
The common cold (viral upper respiratory infection) is the most common pediatric infectious disease, and the incidence is higher in early childhood than in any other period of life (Common Cold; See also Chapter 40). Children younger than 5 years typically have 6–12 colds per year. Approximately 30%–40% are caused by rhinoviruses, of which there are over 100 subtypes. Other culprits include adenoviruses, coronaviruses, enteroviruses, influenza and parainfluenza viruses, and respiratory syncytial virus. Since so many viruses can cause a cold, development of a vaccine has not been possible.

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES
► Clear or mucoid rhinorrhea, nasal congestion, sore throat.
► Possible fever, particularly in younger children (under 5–6 years).
► Possible hoarseness and/or cough.
► Symptoms resolve by 7–10 days, but cough and hoarseness can linger for several weeks afterwards.

► Differential Diagnosis
Rhinosinusitis (acute or chronic), allergic rhinitis, nonallergic rhinitis, influenza, pneumonia, gastroesophageal reflux disease, asthma, and bronchitis.

► Clinical Findings
The patient usually experiences a sudden onset of sore throat followed by clear or mucoid rhinorrhea, nasal congestion, and sneezing. Cough or fever may develop. Although fever is not a prominent feature in older children and adults, in the first 5 or 6 years of life it can be as high as 40.6°C without superinfection. The nose, throat, and TMs may appear red and inflamed. The average duration of symptoms is about 1 week. Nasal secretions tend to become thicker and more purulent after day 2 of infection due to shedding of epithelial cells and influx of neutrophils. This discoloration should not be assumed to be a sign of bacterial rhinosinusitis, unless it persists beyond 10–14 days, by which time the patient should be experiencing significant symptomatic improvement. A mild cough may persist for several weeks following resolution of other symptoms.

► Treatment
Treatment for the common cold is symptomatic (Figure 18–5). Because colds are viral infections, antibiotics are not helpful. Acetaminophen or ibuprofen can relieve fever and pain. Humidification may provide relief for congestion and cough. Nasal saline drops and bulb suctioning may be used for an infant or child unable to blow his or her nose.

Available scientific data suggest that over-the-counter cold and cough medications are generally not effective in children and may be associated with serious adverse effects. Use in children younger than 4 years is not recommended. Antihistamines have not proven effective in relieving cold symptoms in children; in rhinoviral colds, increased levels of histamine are not observed. Oral decongestants may provide symptomatic relief in adults but have not been well studied in children. Studies have shown that most cough medicines are no better than placebo and use of narcotic antitussives is discouraged, as these may be associated with respiratory depression. There is no convincing evidence that naturopathic or alternative therapies are effective in children.

Only time cures the common cold. Education and reassurance may be the most important “therapy” for parents. They should be informed about the expected nature and duration of symptoms, efficacy and potential side effects of medications, and the signs and symptoms of complications of the common cold, such as bacterial rhinosinusitis, bronchiolitis, or pneumonia.

RHINOSINUSITIS
The use of the term rhinosinusitis has replaced sinusitis. Rhinosinusitis acknowledges that the nasal and sinus mucosa are involved in similar and concurrent inflammatory processes.

1. Acute Bacterial Rhinosinusitis
Acute bacterial rhinosinusitis (ABRS) is a bacterial infection of the paranasal sinuses which lasts less than 30 days and in which the symptoms resolve completely. It is almost always preceded by a cold. Other predisposing conditions include allergies and trauma. The diagnosis of ABRS is made when a cold does not improve by 10–14 days or worsens after 5–7 days. The maxillary and ethmoid sinuses are most commonly involved. These sinuses are present at birth. The sphenoid sinuses typically form by the age of 5 years, and the frontal sinuses by age 7–8 years. Frontal sinusitis is unusual before age 10 years.

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES
- Upper respiratory infection symptoms are present 10 or more days beyond onset, or symptoms worsen within 10 days after an initial period of improvement.
- Symptoms may include nasal congestion, nasal drainage, postnasal drainage, facial pain, headache, and fever.
- Symptoms resolve completely within 30 days.

Figure 18–5. Algorithm for acute nasal congestion and rhinosinusitis.
➤ Pathogenesis

Situations which lead to inflammation of sinonasal mucosa and obstruction of sinus drainage underlie the development of rhinosinusitis. A combination of anatomic, mucosal, microbial, and immune factors are believed to be involved. Both viral and bacterial infections play integral roles in the pathogenesis. Viral upper respiratory infections may cause sinus mucosal injury and swelling, resulting in sinus outflow obstruction, loss of ciliary activity, and mucous hypersecretion. The bacterial pathogens that commonly cause acute rhinosinusitis are S pneumoniae, H influenzae (nontypeable), M catarrhalis, and β-hemolytic streptococci.

➤ Clinical Findings

The onset of symptoms in ABRS may be gradual or sudden, and commonly include nasal drainage, nasal congestion, facial pressure or pain, postnasal drainage, hyposmia or anosmia, fever, cough, fatigue, maxillary dental pain, and ear pressure or fullness. The physical examination is rarely helpful in making the diagnosis, as the findings are essentially the same as those in a child with an uncomplicated cold.

In complicated or immunocompromised patients, sinus aspiration and culture by an otolaryngologist should be considered for diagnostic purposes and to facilitate culture-directed antibiotic therapy. Gram stain or culture of nasal aspirates. If the patient is hospitalized because of rhinosinusitis-related complications, blood cultures should also be obtained.

Imaging of the sinuses during acute illness is not indicated except when evaluating for possible complications, or for patients with persistent symptoms which do not respond to medical therapy. As with the physical examination, the radiographic findings of ABRS, such as sinus opacification, fluid, and mucosal thickening, are indistinguishable from those seen in the common cold.

➤ Complications

Complications of ABRS occur when infection spreads to adjacent structures, such as the eye and the brain. S aureus (including methicillin-resistant S aureus) is frequently implicated in complicated ABRS, as well as Streptococcus anginosus (milleri), which has been found to be a particularly virulent organism.

Orbital complications are the most common, arising from the ethmoid sinuses. These complications usually begin as a preseptal cellulitis, but can progress to postseptal cellulitis, subperiosteal abscess, orbital abscess, and cavernous sinus thrombosis. Associated signs and symptoms include eyelid edema, restricted extraocular movements, proptosis, chemosis, and altered visual acuity (see Chapter 16).

The most common complication of frontal sinusitis is osteitis of the frontal bone, also known as Pott’s puffy tumor. Intracranial extension of infection can lead to meningitis and to epidural, subdural, and brain abscesses. Frequently, children with complicated rhinosinusitis have no prior history of sinus infection.

➤ Treatment

For children with cold symptoms that are not improving by 10 days, observation for up to 3 more days or antibiotic therapy may be chosen, depending upon individual circumstances, such as ability to follow up and treat with antibiotics if needed. For children with uncomplicated ABRS who have worsening or severe symptoms (fever of at least 39°C and purulent nasal drainage for at least 3 consecutive days), antibiotic therapy is recommended. Although some discrepancy exists, antibiotics are generally thought to decrease duration and severity of symptoms.

First-line antibiotic therapy should be amoxicillin or amoxicillin-clavulanate. Cefuroxime, cefpodoxime, and cefdinir are recommended for patients with a non–type I hypersensitivity to penicillin, and in most cases may be safely used in patients with an anaphylactoid reaction, as recent studies seem to indicate almost no risk of a serious reaction to second- and third-generation cephalosporins among these patients. Other agents which may be used, particularly in more severe cases where resistant S pneumoniae and H influenzae are suspected, include clindamycin, linezolid, and quinolone antibiotics. Due to high resistance of S pneumoniae and H influenzae, the use of trimethoprim–sulfamethoxazole and azithromycin is not advised.

Duration of therapy should be for 7 days after symptoms have resolved.

Failure to improve after 48–72 hours of antibiotic therapy suggests a resistant organism or potential complication. Second-line therapies should be initiated at this point, or, if the patient is already on amoxicillin–clavulanate or a cephalosporin, intravenous antibiotic therapy should be considered. Imaging and referral for sinus aspiration should be strongly considered as well.

Patients who are toxic, or who have evidence of invasive infection or CNS complications, should be hospitalized immediately. Intravenous therapy with nafcillin or clindamycin plus a third-generation cephalosporin such as cefotaxime should be initiated until culture results become available.

Decongestants, antihistamines, and nasal saline irrigations are frequently used in acute rhinosinusitis to promote drainage. To date, there are no methodologically sound studies supporting their efficacy in children. If used, topical nasal decongestants, such as oxymetazoline or phenylephrine sprays, should not be used for more than 3 days due to risk of rebound edema. Patients with underlying allergic
rhinitis may benefit from intranasal cromolyn or corticosteroid nasal spray.

2. Recurrent or Chronic Rhinosinusitis

Recurrent rhinosinusitis occurs when episodes of ABRS clear for at least 10 days but recur at least four times per year. Chronic rhinosinusitis (CRS) is diagnosed when the child has not cleared the infection in 90 days, but has not developed acute complications. Both symptoms and physical findings are required to support the diagnosis, and CT scan may be useful in making the diagnosis. Although recent meta-analysis evaluations have resulted in recommendations for ABRS, there is a paucity of data for the treatment of recurrent or CRS. Important factors to consider include allergies, anatomic variations, and disorders in host immunity. Mucosal inflammation leading to obstruction is most commonly caused by allergic rhinitis and occasionally by nonallergic rhinitis. There is a great deal of evidence that allergic rhinitis, rhinosinusitis, and asthma are all manifestations of a systemic inflammatory response. Gastroesophageal reflux is also often implicated in CRS. Less commonly, CRS is caused by anatomic variations, such as septal deviation, polypl, or foreign body.

Allergic nasal polyps are unusual in children younger than 10 years and should prompt a workup for cystic fibrosis. In cases of chronic or recurrent pyogenic pansinusitis, poor host resistance (eg, an immune defect, primary ciliary dyskinesia, or cystic fibrosis)—though rare—must be ruled out by immunoglobulin studies, electron microscopy studies of respiratory cilia, nasal nitric oxide measurements if available, a sweat chloride test, and genetic testing (see Chapter 19). Anaerobic and staphylococcal organisms are often responsible for CRS. Evaluation by an allergist and an otolaryngologist may be useful in determining the underlying causes.

Treatment

A. Medical Therapy

Antibiotic therapy is similar to that used for ABRS, but the duration is longer, typically 3–4 weeks. Antimicrobial choice should include drugs effective against staphylococcal organisms. Nasal saline irrigations and intranasal steroid sprays have been shown to be helpful in the reduction of symptoms of CRS.

B. Surgical Therapy

The mainstay of treatment for pediatric CRS is medical management, with appropriate antibiotic therapy and treatment of comorbid conditions such as allergic rhinitis and asthma. Only a small percentage of children will warrant surgical management.

1. Antral lavage—Antral lavage, generally regarded as a diagnostic procedure, may have some therapeutic value. An aspirate or a sample from the maxillary sinus is retrieved under anesthesia. The maxillary sinus is then irrigated. In the very young child, this may be the only procedure performed.

2. Adenoidectomy—Adenoidectomy is thought to be effective in 50%–75% of children with CRS, up to the age of 12 years. The adenoids serve as a reservoir of pathogenic bacteria and may also interfere with mucociliary clearance and drainage. Biofilms have been reported in the adenoids of children with CRS and may explain the resistance of these infections to standard antibiotic therapy.

3. Endoscopic sinus surgery—Endoscopic sinus surgery in children was controversial because of concerns regarding facial growth. However, recent studies have not supported this concern. Endoscopic sinus surgery is reported to be effective in over 80% of cases, and may be indicated if adenoidectomy or balloon dilation is not effective.

4. External drainage—External drainage procedures are reserved for complications arising from ethmoid and frontal sinusitis.

CHOANAL ATRESIA

Choanal atresia occurs in approximately 1 in 7000 live births. The female-male ratio is 2:1, as is the unilateral-bilateral ratio. Bilateral atresia results in severe respiratory distress at birth and requires immediate placement of an oral airway or intubation, and otolaryngology consultation for surgical treatment. Unilateral atresia usually appears later as a unilateral chronic nasal discharge that may be mistaken for CRS. Diagnosis may be suspected if a 6F catheter cannot be passed through the nose and is confirmed by axial CT scan. Approximately 50% of patients with bilateral choanal atresia have CHARGE association (Coloboma, Heart disease, Atresia of the choanae, Retarded growth and retarded development or CNS anomalies, Genital hypoplasia, and Ear anomalies or deafness) (see Chapter 37) or other congenital anomalies.

RECURRENT RHINITIS

Recurrent rhinitis is frequently seen in the office practice of pediatrics. The child is brought in with the chief complaint
of having “one cold after another,” “constant colds,” or “always being sick.” Approximately, two-thirds of these children have recurrent colds; the rest have either allergic rhinitis or recurrent rhinosinusitis.

1. Allergic Rhinitis

Allergic rhinitis is a chronic disorder of the upper airway which is induced by IgE-mediated inflammation secondary to allergen exposure. It is more common in children than in adults and affects up to 40% of children in the United States. It significantly affects quality of life, interfering with physical and social activities, concentration, school performance, and sleep. Allergic rhinitis can contribute to the development of rhinosinusitis, otitis media, and asthma. Symptoms may include nasal congestion, sneezing, rhinorrhea, and itchy nose, palate, throat, and eyes. On physical examination, the nasal turbinates are swollen and may be red or pale pink-purple. Several classes of medications have proven effective in treating allergic rhinitis, including intranasal corticosteroids, oral and intranasal antihistamines, leukotriene antagonists, and decongestants. Ipratropium nasal spray may also be used as an adjunctive therapy. Nasal saline rinses are helpful to wash away allergens. Recent studies have indicated that use of intranasal steroid sprays may not only decrease the impairment caused by allergic rhinitis symptoms, but also help prevent progression to more severe disease and decrease the risk of related comorbidities such as asthma and sleep-disordered breathing.

2. Nonallergic Rhinitis

Nonallergic rhinitis also causes rhinorrhea and nasal congestion, but does not seem to involve an immunologic reaction. Its mechanism is not well understood. Triggers can include sudden changes in environmental temperature, air pollution, and other irritants such as tobacco smoke. Medications can also be associated with nonallergic rhinitis. Nasal decongestant sprays, when used for long periods of time, can cause rhinitis medicamentosa, which is a rebound nasal congestion which can be very difficult to treat. Oral decongestants, nasal corticosteroids, antihistamines, and ipratropium spray have all been shown to offer symptomatic relief.

Web Resources

EPISTAXIS

The nose is a highly vascular structure. In most cases, epistaxis (nosebleed) arises from the anterior portion of the nasal septum (Kiesselbach area). It is often due to dryness, nose rubbing, nose blowing, or nose picking. Examination of the anterior septum usually reveals a red, raw surface with fresh clots or old crusts. Presence of telangiectasias, hemangiomas, or varicosities should also be noted. If a patient has been using a nasal corticosteroid spray, check the patient’s technique to make sure he or she is not directing the spray toward the septum. If proper technique does not reduce the nosebleeds, the spray should be discontinued.

In fewer than 5% of cases, epistaxis is caused by a bleeding disorder such as von Willebrand disease. A hematologic workup is warranted if any of the following is present: family history of a bleeding disorder; medical history of easy bleeding, particularly with circumcision or dental extraction; spontaneous bleeding at any site; bleeding that lasts for more than 30 minutes or blood that will not clot with direct pressure by the physician; onset before age 2 years; or a drop in hematocrit due to epistaxis. High blood pressure may rarely predispose to prolonged nosebleeds in children.

Juvenile nasopharyngeal angiofibroma (JNA) is a benign, but often aggressive, tumor that tends to bleed and may present as recurrent epistaxis (45%–60%). JNA is only seen in males; females with JNA should undergo genetic testing. CT and MRI are diagnostic.

Treatment

The patient should sit up and lean forward so as not to swallow the blood. Swallowed blood may cause nausea and hematemesis. The nasal cavity should be cleared of clots by gentle blowing. The soft part of the nose below the nasal bones is pinched and held firmly enough to prevent arterial blood flow, with pressure over the bleeding site (anterior septum) being maintained for 5 minutes. For persistent bleeding, a one-time only application of oxymetazoline into the nasal cavity may be helpful. If bleeding continues, the bleeding site needs to be visualized. A small piece of gelatin sponge (Gelfoam) or collagen sponge (Surgicel) can be inserted over the bleeding site and held in place.

Friability of the nasal vessels is often due to dryness and can be decreased by increasing nasal moisture. This can be accomplished by daily application of a water-based ointment to the nose. A pea-sized amount of ointment is placed just inside the nose and spread by gently squeezing the nostrils. Twice-daily nasal saline irrigation and humidifier use may also be helpful. Aspirin and ibuprofen should be avoided, as should nose picking and vigorous nose blowing. Otolaryngology referral is indicated for refractory cases. Cautery of the nasal vessels is reserved for treatment failures.
NASAL INFECTION

A nasal furuncle is an infection of a hair follicle in the anterior nares. Hair plucking or nose picking can provide a route of entry. The most common organism is *S. aureus*. A furuncle presents as an exquisitely tender, firm, red lump in the anterior nares. Treatment includes dicloxacillin or cephalaxin orally for 5 days to prevent spread. The lesion should be gently incised and drained as soon as it points with a sterile needle. Topical antibiotic ointment may be of additional value. Because this lesion is in the drainage area of the cavernous sinus, the patient should be followed closely until healing is complete. Parents should be advised never to pick or squeeze a furuncle in this location—and neither should the physician. Associated cellulitis or spread requires hospitalization for administration of intravenous antibiotics.

A nasal septal abscess usually follows nasal trauma or a nasal furuncle. Examination reveals fluctuant gray septal swelling, which is usually bilateral. The possible complications are the same as for nasal septal hematoma (see following discussion). In addition, spread of the infection to the CNS is possible. Treatment consists of immediate hospitalization, incision and drainage by an otolaryngologist, and antibiotic therapy.

NASAL TRAUMA

Newborn infants rarely present with subluxation of the quadrangular cartilage of the septum. In this disorder, the top of the nose deviates to one side, the inferior septal border deviates to the other side, the columella leans, and the nasal tip is unstable. This disorder must be distinguished from the more common transient flattening of the nose caused by the birth process. In the past, physicians were encouraged to reduce all subluxations in the nursery. Otolaryngologists are more likely to perform the reduction under anesthesia for more difficult cases.

After nasal trauma, it is essential to examine the inside of the nose in order to rule out hematoma of the nasal septum, as this can quickly lead to septal necrosis, causing permanent nasal deformity. This diagnosis is confirmed by the abrupt onset of nasal obstruction following trauma and the presence of a boggy, widened nasal septum. The normal nasal septum is only 2–4 mm thick. A cotton swab can be used to palpate the septum. Treatment consists of immediate referral to an otolaryngologist for drainage and packing of the nose.

Most blows to the nose result in epistaxis without fracture. A persistent nosebleed after trauma, crepitus, instability of the nasal bones, and external deformity of the nose indicate fracture. Septal injury cannot be ruled out by radiography, and can only be ruled out by careful intranasal examination. Patients with suspected nasal fractures should be referred to an otolaryngologist for definitive therapy. Since the nasal bones begin healing immediately, the child must be seen by an otolaryngologist within 48–72 hours of the injury to allow time to arrange for fracture reduction before the bones become immobile.

FOREIGN BODIES IN THE NOSE

If this diagnosis is delayed, unilateral foul-smelling rhinorrhea, halitosis, bleeding, or nasal obstruction often result.

There are many ways to remove nasal foreign bodies. The obvious first maneuver is vigorous nose blowing if the child is old enough. The next step in removal requires nasal decongestion, good lighting, correct instrumentation, and physical restraint. Topical tetracaine or lidocaine may be used for anesthesia in young children. Nasal decongestion can be achieved by topical phenylephrine or oxymetazoline. When the child is properly restrained, most nasal foreign bodies can be removed using a pair of alligator forceps or right-angle instrument through an operating head otoscope. If the object seems unlikely to be removed on the first attempt, is wedged in, or is quite large, the patient should be referred to an otolaryngologist rather than worsening the situation through futile attempts at removal.

Because the nose is a moist cavity, the electrical current generated by disk-type batteries—such as those used in clocks, watches, and hearing aids—can cause necrosis of mucosa and cartilage destruction in less than 4 hours. Batteries constitute a true foreign body emergency.

THE THROAT & ORAL CAVITY

ACUTE STOMATITIS

1. Recurrent Aphthous Stomatitis

Aphthous ulcers, or canker sores, are small painful ulcers (3–10 mm) usually found on the inner aspect of the lips or on the tongue; rarely they may appear on the tonsils or palate. There is usually no associated fever or cervical adenopathy. They can last 1–2 weeks and may recur numerous times throughout life. The cause is unknown, although an allergic or autoimmune basis is suspected.

A topical corticosteroid, such as triamcinolone dental paste, may reduce duration of the lesion. Pain can also be reduced by eating a bland diet, avoiding salty or acidic foods and juices, and by taking acetaminophen or ibuprofen. A recent Cochrane review was unable to promote a single systemic treatment for those unresponsive to local therapy.

Less common causes of recurrent oral ulcers include Behçet disease, familial Mediterranean fever, and PFAPA syndrome (Periodic Fever, Aphthous stomatitis, Pharyngitis, and cervical Adenopathy). PFAPA syndrome was first described in 1987, and its cause is unknown, although an immune etiology is suspected. It usually begins before the...
age of 5 years, continues through adolescence, and then spontaneously resolves. Fever and other symptoms recur at regular intervals. Episodes last approximately 5 days and are not associated with other URI symptoms or illnesses. Episodes may be dramatically improved with prednisone bursts, but recurrences typically continue. PFAPA may resolve with prolonged cimetidine treatment. Tonsillectomy has been shown to be effective in curing this condition. Otolaryngology referral is appropriate.

A diagnosis of Behçet disease requires two of the following: genital ulcers, uveitis, and erythema nodosum–like lesions. Patients with Mediterranean fever usually have a positive family history, serosal involvement, and recurrent fever.

2. Herpes Simplex Gingivostomatitis
(See Chapter 40 Infections: Viral & Rickettsial)

3. Thrush (See Chapter 43 Infections: Parasitic & Mycotic)

4. Traumatic Oral Ulcers
Mechanical trauma most commonly occurs on the buccal mucosa secondary to biting by the molars (see Chapter 40 Infections: Viral & Rickettsial). Thermal trauma, from very hot foods, can also cause ulcerative lesions (see Chapter 43 Infections: Parasitic & Mycotic). Chemical ulcers can be produced by mucosal contact with aspirin or other caustic agents. Oral ulcers can occur with leukemia or on a recurrent basis with cyclic neutropenia.

PHARYNGITIS

Figure 18–6 is an algorithm for the management of a sore throat.

1. Acute Viral Pharyngitis
Over 90% of sore throats and fever in children are due to viral infections. The findings seldom point toward any particular viral agent, but four types of viral pharyngitis are sufficiently distinctive to warrant discussion below.

Clinical Findings

A. Infectious Mononucleosis

Findings include exudative tonsillitis, generalized cervical adenitis, and fever, usually in patients older than 5 years. A palpable spleen or axillary adenopathy increases the likelihood of the diagnosis. The presence of more than 10% atypical lymphocytes on a peripheral blood smear or a positive mononucleosis spot test supports the diagnosis, although these tests are often falsely negative in children younger than 5 years. Epstein-Barr virus serology showing an elevated IgM-capsid antibody is definitive. Amoxicillin is contraindicated in patients suspected of having mononucleosis because the drug often precipitates a rash.

B. Herpangina

Herpangina ulcers are classically 3 mm in size, surrounded by a halo and are found on the anterior tonsillar pillars, soft palate, and uvula; the anterior mouth and tonsils are spared. Herpangina is caused by the Coxsackie A group of viruses. Enteroviral polymerase chain reaction testing is widely available, but not typically indicated, as herpangina is a self-limited illness.

C. Hand, Foot, and Mouth Disease

This entity is caused by several enteroviruses, one of which (enterovirus 71) can rarely cause encephalitis. Ulcers occur anywhere in the mouth. Vesicles, pustules, or papules may be found on the palms, soles, interdigital areas, and buttocks. In younger children lesions may be seen on the distal extremities and even the face.

D. Pharyngoconjunctival Fever

This disorder is caused by an adenovirus and often is epidemic. Exudative tonsillitis, conjunctivitis, lymphadenopathy, and fever are the main findings. Treatment is symptomatic.

2. Acute Bacterial Pharyngitis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Sore throat
- At least one of the following:
  a. Cervical lymphadenopathy (lymph nodes tender or > 2 cm)
  b. Tonsillar exudates
  c. Positive group A β-hemolytic streptococcus culture
  d. Fever > 38.3°C
Pharyngitis
Assess degree of illness

Mild to moderate

Afebrile with upper respiratory tract infection
Child febrile or tender cervical nodes or tonsillar exudates or *S pyogenes* exposure or family history of rheumatic fever

Symptomatic care

Rapid strep test

Negative

Send throat culture

Negative

Penicillin VK 50–70 mg/kg/d in 3 divided doses; benzathine penicillin 600,000 units IM if < 27 kg, 1.2 million units if > 27 kg, single dose; for penicillin-allergic patients use azithromycin

Cure

Failure or relapse in < 1 wk

Severe pharyngitis

ENT consult

Unilateral swelling of tonsils

Bilateral swelling of tonsils and airway problems during sleep

Airway compromised

Drain surgically if abscess or treat intravenously if cellulitis

1. Throat culture and rapid test
2. Mononucleosis diagnostic tests (CBC, Monospot, EBV-IgM)

Urgent ENT assessment

Admit for observation

Persistent group A *Streptococcus*

Counsel about contact sports

Clindamycin for 10 d

Mononucleosis test positive

Repeat throat culture and consider serologic testing for mononucleosis

 Figure 18–6. Algorithm for pharyngitis. CBC, complete blood count; EBV, Epstein-Barr virus; ENT, ear, nose, and throat.
Differential Diagnosis

Viral pharyngitis, infectious mononucleosis, bacterial pharyngitis other than streptococcal, diphtheria, and peritonsillar abscess.

Approximately 20%–30% of children with pharyngitis have a group A streptococcal infection. It is most common in children between 5 and 15 years in the winter or early spring. Less common causes of bacterial pharyngitis include *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, groups C and G streptococci, and *Arcanobacterium hemolyticum*. Of the five, *M pneumoniae* is by far the most common and may cause over one-third of all pharyngitis cases in adolescents and adults.

Clinical Findings

Sudden onset of sore throat, fever, tender cervical adenopathy, palatal petechiae, a beefy-red uvula, and a tonsillar exudate suggest streptococcal infection. Other symptoms may include headache, stomachache, nausea, and vomiting. The only way to make a definitive diagnosis is by throat culture or rapid antigen test. Rapid antigen tests are very specific, but have a sensitivity of only 85%–95%. Therefore, a positive test indicates *S. pyogenes* infection, but a negative result requires confirmation by performing a culture. Diagnosis is important because untreated streptococcal pharyngitis can result in acute rheumatic fever, glomerulonephritis, and supplicative complications (eg, cervical adenitis, peritonsillar abscess, otitis media, cellulitis, and septicemia). The presence of conjunctivitis, cough, hoarseness, symptoms of upper respiratory infection, anterior stomatitis, ulcerative lesions, viral rash, and diarrhea should raise suspicion of a viral etiology.

 Occasionally, a child with group A streptococcal infection develops scarlet fever within 24–48 hours after the onset of symptoms. Scarlet fever is a diffuse, finely papular, erythematous eruption producing a bright red discoloration of the skin, which blanches on pressure. The rash is more intense in the skin creases. The tongue has a strawberry appearance.

A controversial but possible complication of streptococcal infections is pediatric autoimmune neuropsychiatric disorders associated with *Streptococcus* (PANDAS). PANDAS is a relatively newly recognized condition. It describes a subset of pediatric patients who experience a sudden onset of obsessive-compulsive disorder and/or tics, or worsening of such symptoms in children who previously had these, following a strep infection.

Treatment

Suspected or proven group A streptococcal infection should be treated with penicillin (oral or intramuscular) or amoxicillin as outlined in Table 18–4. For patients allergic to penicillin, alternative treatments include cephalexin, azithromycin, and clindamycin. Tetracyclines, sulfonamides (including trimethoprim-sulfamethoxazole) and quinolones should not be used for treating GAS infections.

Repeat culture after treatment is not recommended and is indicated only for those who remain symptomatic, have a recurrence of symptoms, or have had rheumatic fever. Of note, children who have had rheumatic fever are at a high risk of recurrence. The treatment of group A streptococcal pharyngitis is presented in Table 18–4.

Eradication of Carrier State

| Clindamycin | 20 mg/kg/d in 3 divided doses for 10 d | Most effective |
| Cephalexin | 25–50 mg/kg/d in 2 divided doses for 10 d | Also effective |
| Penicillin + Rifampin | See above penicillin doses; Rifampin 20 mg/kg/d twice daily for final 4 d | |
risk of recurrence if future group A strep infections are inadequately treated. In this group of patients, long-term antibiotic prophylaxis is recommended, sometimes lifelong in patients with residual rheumatic heart disease. (See Chapter 20.)

In general, the carrier state is harmless, self-limited (2–6 months), and not contagious. An attempt to eradicate the carrier state is warranted only if the patient or another family member has frequent streptococcal infections, or if a family member or patient has a history of rheumatic fever or glomerulonephritis. If eradication is chosen, a course of clindamycin for 10 days or rifampin for 5 days should be used.

In the past, daily penicillin prophylaxis was occasionally recommended; however, because of concerns about the development of drug resistance, tonsillectomy is now preferred for patients with recurrent streptococcal tonsillitis.

Web Resources

PERITONSILLAR CELLULITIS OR ABSCESS (QUINSY)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► Severe sore throat.
► Unilateral tonsillar swelling.
► Deviation of the uvula.
► Trismus (limited mouth opening).

Tonsillar infection occasionally penetrates the tonsillar capsule, spreading to the surrounding tissues, causing peritonsillar cellulitis. If untreated, necrosis occurs and a peritonsillar abscess forms. The most common pathogen is β-hemolytic streptococcus, but others include group D streptococcus, S pneumoniae, and anaerobes.

The patient complains of a severe sore throat even before the physical findings become marked. A high fever is usually present, and the process is almost always unilateral. The tonsil bulges medially, and the anterior tonsillar pillar is prominent. The soft palate and uvula on the involved side are edematous and displaced toward the uninvolved side.

As the infection progresses, trismus, ear pain, dysphagia, and drooling may occur. The most serious complication of untreated peritonsillar abscess is a lateral pharyngeal abscess.

It is often difficult to differentiate peritonsillar cellulitis from abscess. In some children, it is possible to aspirate or drain the peritonsillar space to diagnose and treat an abscess. If drainage is not possible and there are no airway symptoms, it is reasonable to admit a child for 12–24 hours of intravenous antimicrobial therapy. Aggressive treatment of cellulitis can usually prevent suppuration. Therapy with a penicillin or clindamycin is appropriate. Failure to respond to therapy during the first 12–24 hours indicates a high probability of abscess formation and otolaryngology consultation is indicated. Recurrent peritonsillar abscesses are so uncommon (7%) that routine tonsillectomy for a single incident is not indicated unless other tonsillectomy indications exist.

RETROPHARYNGEAL ABSCESS

Retropharyngeal lymph nodes, which drain the adenoids, nasopharynx, and paranasal sinuses, can become infected, commonly due to β-hemolytic streptococci and S aureus. If this pyogenic adenitis goes untreated, a retropharyngeal abscess forms. This occurs most commonly during the first 2 years of life. After this age, the most common cause of retropharyngeal abscess is superinfection of a penetrating injury of the posterior wall of the oropharynx.

The diagnosis of retropharyngeal abscess should be strongly suspected in a child with fever, respiratory symptoms, and neck hyperextension. Dysphagia, drooling, dyspnea, and gurgling respirations are also found. Prominent swelling on one side of the posterior pharyngeal wall is characteristic. Swelling usually stops at the midline because a medial raphe divides the prevertebral space. On lateral neck x-ray, the retropharyngeal tissues are wider than the C4 vertebral body. But plain films are not specific; a CT scan with contrast is more helpful.

Although a retropharyngeal abscess is a surgical emergency, frequently it cannot be distinguished from retropharyngeal adenitis. Immediate hospitalization and intravenous antimicrobial therapy with a semisynthetic penicillin or clindamycin is the first step for most cases. In most instances, a period of 12–24 hours of antimicrobial therapy will help differentiate the two entities. In the child with adenitis, fever will decrease and oral intake will improve. A child with retropharyngeal abscess will typically not improve. A surgeon should incise and drain the abscess under general anesthesia to prevent its extension. Immediate surgical drainage is required whenever there is concern for airway compromise.

LUDWIG ANGINA

Ludwig angina is a rapidly progressive cellulitis of the submandibular space that can cause airway obstruction and death.
The submandibular space extends from the mucous membrane of the floor of the mouth to the muscular and fascial attachments of the hyoid bone. This infection is unusual in infants and children. The initiating factor in over 50% of cases is dental disease, including abscesses and extraction. Some patients have a history of injury to the floor of the mouth. Group A strep is the most common organism identified. Symptoms include fever and tender swelling of the floor of the mouth. The tongue can become tender and inflamed. Upward displacement of the tongue may cause dysphagia, drooling, and airway obstruction.

Treatment consists of high-dose intravenous clindamycin or ampicillin plus nafcillin until the culture results and sensitivities are available. Because the most common cause of death in Ludwig angina is sudden airway obstruction, the patient must be monitored closely in the intensive care unit and intubation provided for progressive respiratory distress. An otolaryngologist should be consulted for airway evaluation and management, and to perform a drainage procedure if needed.

**ACUTE CERVICAL ADENITIS**

Local infections of the ear, nose, and throat can involve a regional lymph node and cause abscess formation. The typical case involves a unilateral, solitary, anterior cervical node. About 70% of these cases are due to beta-hemolytic streptococcal infection, 20% to staphylococci, and the remainder to viruses, atypical mycobacteria, and *Bartonella henselae*. MRSA must also be considered.

The initial evaluation of cervical adenitis should generally include a rapid group A streptococcal test, and a complete blood count with differential looking for atypical lymphocytes. A purified protein derivative skin test, looking for nontuberculous mycobacteria, should also be considered. If multiple enlarged nodes are found, a rapid mononucleosis test is useful. Early treatment with antibiotics prevents many cases of adenitis from progressing to suppuration. However, once abscess formation occurs, antibiotic therapy alone is often insufficient and a drainage procedure may be necessary. Because of the increase in community-acquired MRSA, it is a prudent to send a specimen for culture and sensitivity.

Cat-scratch disease, caused by *B henselae*, causes indolent (“cold”) adenopathy. The diagnosis is supported if a primary papule is found at the scratch site on the face. In over 90% of patients, there is a history of contact with kittens. The node is usually only mildly tender but may, over a month or more, suppurate and drain. About one-third of children have fever and malaise; rarely neurologic sequelae and prolonged fever occur. Cat-scratch disease can be diagnosed by serologic testing, but testing is not always confirmatory. If blood is to be drawn, one should wait 2–8 weeks after onset of symptoms. Because most enlarged lymph nodes infected with *B henselae* spontaneously regress within 1–3 months, the benefit of antibiotics is controversial. In a placebo-controlled trial, azithromycin for 5 days caused a more rapid decrease in node size. Other drugs likely to be effective include rifampin, trimethoprim-sulfamethoxazole, erythromycin, clarithromycin, doxycycline*, ciprofloxacin*, and gentamicin (*be aware of age restrictions*).

Cervical lymphadenitis can also be caused by nontuberculous mycobacterial species or *Mycobacterium avium* complex. Mycobacterial disease is unilateral and may involve several matted nodes. A characteristic violaceous appearance may develop over a prolonged period of time without systemic signs or much local pain. Atypical mycobacterial infections are often associated with positive purified protein derivative skin test reactions less than 10 mm in diameter, and a second-strength (250-test-unit) purified protein derivative skin test is virtually always positive.

**Differential Diagnosis**

**A. Neoplasms and Cervical Nodes**

Malignant tumors usually are not suspected until adenopathy persists despite antibiotic treatment. Classically, malignant lymph nodes are painless, nontender, and firm to hard in consistency. They may be fixed to underlying tissues. They may occur as a single node, as unilateral nodes in a chain, bilateral cervical nodes, or as generalized adenopathy. Common malignancies that may manifest in the neck include lymphoma, rhabdomyosarcoma, and thyroid carcinoma.

**B. Imitators of Adenitis**

Several structures in the neck can become infected and resemble a lymph node. The first three masses are of congenital origin.

1. **Thyroglossal duct cyst**—These are in the midline, usually located near the level of the hyoid bone. Thyroglossal duct cysts move upward when the tongue is protruded or with swallowing. Occasionally, a thyroglossal duct cyst may have a sinus tract with an opening just lateral to the midline. When infected, these can become acutely swollen and inflamed.

2. **Branchial cleft cyst**—These masses are found along the anterior border of the sternocleidomastoid muscle and...
are smooth and fluctuant. Sometimes a branchial cleft cyst may be attached to the overlying skin by a small dimple or a draining sinus tract. When infected, they can become a tender mass 3–5 cm in diameter.

3. Lymphatic malformation—Most lymphatic cysts are located in the posterior triangle just above the clavicle. These are soft and compressible and can be transilluminated. Over 60% of lymphatic malformations are noted at birth; the remaining malformations are usually seen by the age of 2 years. If these become large enough, they can compromise the patient’s ability to swallow and breathe.

4. Parotitis—The most common pitfall is confusing parotitis for cervical adenitis. The parotid saliva gland crosses the angle of the jaw. Parotitis may be bacterial or viral and may occur unilaterally or bilaterally. Mumps was once the most common cause of viral parotitis, but because of routine vaccinations, parainfluenza is the primary viral cause in the United States. An amylase level will be elevated in parotitis.

5. Ranula—A ranula is a cyst in the floor of the mouth caused by obstruction of the sublingual salivary gland. A “plunging” ranula extends through the mylohyoid muscle and can present as a neck mass.

6. Sternocleidomastoid muscle hematoma—Also known as fibromatosis colli, these are noted at age 2–4 weeks. On examination, the mass is found to be part of the muscle body and not movable. An associated torticollis usually confirms the diagnosis. A neck ultrasound can help confirm the diagnosis. Treatment involves physical therapy, with range of motion exercises.

SNORING, MOUTH BREATHING, & UPPER AIRWAY OBSTRUCTION

The American Academy of Otolaryngology-Head and Neck Surgery (AAO-HNS) defines sleep-disordered breathing (SDB) as an abnormal respiratory pattern during sleep that includes snoring, mouth breathing, and pauses in breathing. SDB encompasses a spectrum of disorders that ranges in severity from snoring to obstructive sleep apnea. SDB is a presumptive diagnosis; OSA can be diagnosed only by polysomnography (PSG).

In 2012, the American Academy of Pediatrics (AAP) updated their clinical practice guideline for the diagnosis and management of uncomplicated childhood obstructive sleep apnea syndrome. The guideline emphasizes that pediatricians should screen all children for snoring. If the child exhibits additional signs and symptoms of SDB, referral for a sleep study is recommended, but referral to an otolaryngologist or sleep specialist is also an option. The American Academy of Sleep Medicine (AASM) has similar recommendations.

Polysomnography

The gold standard for diagnosis of OSA is a polysomnogram (PSG), commonly called a “sleep study.” A patient’s history and clinical examination cannot predict the presence or severity of OSA. Similarly, an overnight oximetry study is a poor screening test for OSA, as it may detect patients with severe disease but miss those with milder forms, since obstructive respiratory events can occur without oxygen desaturations. The criteria for diagnosing OSA differ between children and adults. An obstructive event occurs when airflow stops despite persistence of respiratory effort. A hypopnea is counted when airflow and respiratory effort decrease with an associated oxygen desaturation or arousal. Normative values for children are just being established. The AASM states that for children, the occurrence of more than one apneic or hypopneic event per hour with duration of at least two respiratory cycles is abnormal. However, the AASM has qualified its recommendation, stating that the criteria may be modified once more comprehensive data become available. One study of children aged 6–11 years found that a respiratory disturbance index of at least one event per hour, when associated with a 3% oxygen desaturation, was associated with daytime sleepiness and learning problems. If oxygen desaturations were absent, a respiratory disturbance index of five events per hour was associated with clinical symptoms.

Although an obstructive apnea index greater than one event per hour may be statistically significant, whether it is clinically relevant remains unclear. Children with an apnea-hypopnea index of greater than five events per hour appear to have clinically significant OSA. The dilemma is how to manage children with an apnea-plus-hypopnea index of more than one but fewer than five events per hour, as some of these children experience neurocognitive symptoms. Notably, many studies have shown little correlation between the severity of OSA by PSG and neuropsychological morbidity.

Clinical Evaluation & Management

The AAO-HNS has developed clinical guidelines to help otolaryngologists determine when to proceed with surgical treatment (usually adenotonsillectomy) or request a PSG. A PSG is generally recommended for children with suspected sleep apnea if they have any of the following comorbid conditions: obesity, Down syndrome, craniofacial abnormalities, neuromuscular disorders, sickle cell disease, or mucopolysaccharidosis. PSG is also recommended for children without the above comorbidities if the need for surgery is uncertain, or if there is discordance between tonsillar size on physical examination and the reported severity of symptoms.

Most pediatric otolaryngologists perform adenotonsillectomy in healthy patients with SDB without obtaining a
An adenotonsillectomy without PSG is usually recommended in a healthy child if the following are present:

1. **Nighttime symptoms**: habitual snoring along with gasping, pauses, or labored breathing. Other symptoms which may be related to SDB include night terrors, sleepwalking, and secondary enuresis.
2. **Daytime symptoms**: unrefreshed sleep, attention deficit, hyperactivity, emotional lability, temperamental behavior, poor weight gain, and daytime fatigue. Other signs include daytime mouth breathing or dysphagia.
3. **Enlarged tonsils**.

If the three findings cannot be confirmed, but the child has other indications for an adenotonsillectomy—that is, recurrent tonsillitis or markedly enlarged (4+) tonsils with dysphagia—surgery is also warranted.

Figure 18–7 is an algorithm for management of SDB complaints in an otherwise healthy child. The pathway relies on clinical symptoms and tonsil size. The most commonly used grading scale for tonsil size ranges from 0 to 4. With grade 0 the tonsils are small and contained within the tonsillar fossa; in grade 4 the tonsils are so large they almost touch (“kissing”). Of note, tonsil size alone does not predict the presence of significant SDB. Children without significant tonsil hypertrophy may still have SDB. Factors such as low muscle tone can contribute to an individual’s propensity to experience SDB. Although the pathway states that an asymptomatic child with markedly enlarged tonsils (4+) should undergo PSG, a period of observation is reasonable. One's clinical suspicion of SDB should be heightened if a child has enlarged tonsils, especially if the parents cannot provide a reliable history. If the child has no clinical symptoms and the tonsils are only moderately enlarged (3+), observation is appropriate. Educating the parents about the risks of SDB and what to look for is paramount.

A polysomnographic study is recommended for a child who has no adenotonsillar hypertrophy or nasal obstruction, but has significant symptoms of SDB. Other conditions, especially a periodic limb movement disorder, may mimic the daytime symptoms of SDB. If a PSG indicates OSA in a child without tonsillar hypertrophy, a complete evaluation of the upper airway by awake flexible laryngoscopy should be performed to look for other possible sites of obstruction: nose, nasopharynx (adenoid), hypopharynx (base of tongue or lingual tonsils), and larynx. The adenoid can also be assessed with a lateral neck x-ray. Alternative methods to evaluate a child for anatomical sites of obstruction include sedated cine MRI of the upper airway or drug-induced sleep endoscopy (DISE).

A recent randomized prospective study on adenotonsillectomy outcomes (CHAT Study) demonstrated overall success at 79% for an adenotonsillectomy. Success was defined as AHI < 2 and obstructive apnea index of less than 1 event an hour. Obese children, black ethnicity, and an AHI more than 4.7 events an hour were less likely to be cured. Interestingly, 47% of the children in the watchful waiting group had

![Figure 18–7. Algorithm for evaluation of snoring in a healthy child.](attachment:Figure_18–7.png)
spontaneous resolution of their OSA at 7 months. Children who had mild OSA or normal weight were more likely to improve spontaneously.

As for postoperative PSG, the AASM and AAP agree that a child with mild OSA (typically fewer than five obstructive events an hour) does not require a follow-up study. However, those with persistent symptoms, more severe OSA, obesity, or other comorbidities should routinely have a postoperative study.

**Complications & Sequelae**

The importance of diagnosing SDB in children cannot be underestimated. SDB has been associated with problems in a multitude of realms, including social, behavioral, and neurocognitive. It has been shown to significantly impact quality of life and has been associated with growth impairment and cardiovascular complications. Recent studies also suggest that SDB is associated with systemic inflammation.

**Web Resources**

**TONSILLECTOMY & ADENOIDECTOMY**

**Tonsillectomy**

A tonsillectomy, with or without adenoidectomy, is most often performed for either hypertrophy or recurrent infections. The most common indication for adenotonsillectomy is adenotonsillar hypertrophy associated with an obstructive breathing pattern during sleep (see earlier discussion of OSA and SDB). Adenotonsillar hypertrophy may also cause dysphagia or dental malocclusion. Rarely, hypertrophied tonsils may lead to pulmonary hypertension or cor pulmonale.

Recurrent tonsillitis is the second most common reason for tonsillectomy. Tonsillitis is considered “recurrent” when a child has seven or more documented infections in 1 year, five per year for 2 years, or three per year for 3 years. For an infection to be considered clinically significant, there must be a sore throat and at least one of the following clinical features: cervical lymphadenopathy (tender lymph nodes or > 2 cm), OR tonsillar exudate, OR positive culture for group A β-hemolytic streptococcus, OR temperature greater than 38.3°C.

Tonsillectomy is reasonable with fewer infections if the child has missed multiple school days due to infection, has a complicated course, or under other circumstances such as recurrent peritonsillar abscess, persistent streptococcal carrier state, or multiple antibiotic allergies. Unless neoplasm is suspected, tonsil asymmetry is not an indication.

A new indication for tonsillectomy is PFAPA syndrome (see earlier section on Recurrent Aphthous Stomatitis), in which fever recurs predictably, typically every 4–8 weeks. Tonsillectomy has been shown to be an effective treatment.

**Web Resources**

such as mandibular growth abnormalities and dental malocclusion, speech abnormalities, persistent MEE, recurrent otitis media, and CRS.

Complications of Tonsillectomy & Adenoidectomy

The mortality rate associated with tonsillectomy and adenoidectomy is reported to approximate that of general anesthesia alone. The rate of hemorrhage varies between 0.1% and 8.1%, depending on the definition of hemorrhage; the rate of postoperative transfusion is 0.04%. Other potential complications include permanently hypernasal speech (< 0.01%) and, more rarely, nasopharyngeal stenosis, atlantoaxial subluxation, mandibular condyle fracture, and psychological trauma.

Contraindications to Tonsillectomy & Adenoidectomy

A. Palatal Abnormalities

Adenoids should not be removed completely in a child with a cleft palate or submucous cleft palate because of the risk of velopharyngeal incompetence which may cause hypernasal speech and nasal regurgitation. If needed, a partial adenoidectomy can be performed in at-risk children. A bifid uvula can be a sign of a palatal abnormality.

B. Bleeding Disorder

When suspected, bleeding disorders must be diagnosed and treated prior to surgery.

C. Acute Tonsillitis

An elective tonsillectomy and adenoidectomy can often be postponed until acute tonsillitis is resolved. Urgent tonsillectomy may occasionally be required for tonsillitis unresponsive to medical therapy.

DISORDERS OF THE LIPS

1. Labial Sucking Tubercle

A young infant may present with a small callus in the mid-upper lip. It usually is asymptomatic and disappears after cup feeding is initiated.

2. Cheilitis

Dry, cracked, scaling lips are usually caused by sun or wind exposure. Contact dermatitis from mouthpieces or various woodwind or brass instruments has also been reported. Licking the lips exacerbates cheilitis. Liberal use of lip balm gives excellent results.

3. Inclusion Cyst

Inclusion or mucous retention cysts are due to obstruction of mucous glands or other mucous membrane structures, such as minor salivary glands. In the newborn, they occur on the hard palate or gums and are called Epstein pearls. These resolve spontaneously in 1–2 months. In older children, inclusion cysts usually occur on the palate, uvula, or tonsillar pillars. They appear as taut yellow sacs varying in size from 2 to 10 mm. Inclusion cysts that do not resolve spontaneously may undergo incision and drainage. Occasionally, a mucous cyst on the lower lip (mucocele) will require excision for cosmetic reasons.

DISORDERS OF THE TONGUE

1. Geographic Tongue (Benign Migratory Glossitis)

This condition of unknown etiology occurs in 1%–2% of the population with no age, sex, or racial predilection. It is characterized by irregularly shaped patches on the tongue that are devoid of papillae and surrounded by parakeratotic reddish borders. The pattern changes as alternating regeneration and desquamation occurs. The lesions are generally asymptomatic and require no treatment.

2. Fissured Tongue (Scrotal Tongue)

This condition is marked by numerous irregular fissures on the dorsum of the tongue. It occurs in approximately 1% of the population and is usually a dominant trait. It is also frequently seen in children with trisomy 21.

3. Coated Tongue (Furry Tongue)

The tongue becomes coated if mastication is impaired and the patient is limited to a liquid or soft diet. Mouth breathing, fever, or dehydration can accentuate the process.

4. Macroglossia

Tongue hypertrophy and protrusion may be due to trisomy 21, Beckwith-Wiedemann syndrome, glycogen storage diseases, cretinism, mucopolysaccharidoses, lymphangioma, or hemangioma. Tongue reduction procedures should be considered in otherwise healthy subjects if macroglossia affects airway patency.

HALITOSIS

Bad breath is usually due to acute stomatitis, pharyngitis, rhinosinusitis, nasal foreign body, or dental hygiene problems. In older children and adolescents, halitosis can be a manifestation of CRS, gastric bezoar, bronchiectasis, or lung abscess. The presence of orthodontic devices or dentures can cause
halitosis if good dental hygiene is not maintained. Halitosis can also be caused by decaying food particles embedded in cryptic tonsils. Mouthwashes and chewable breath fresheners give limited improvement. Treatment of the underlying cause is indicated, and a dental referral may be in order.

**SALIVARY GLAND DISORDERS**

1. **Parotitis**

A first episode of parotitis may safely be considered to be of viral origin, unless fluctuance is present. Mumps was the leading cause until adoption of vaccination; now the leading viruses are parainfluenza and Epstein-Barr virus. HIV infection should be considered if the child is known to be at risk.

2. **Suppurative Parotitis**

Suppurative parotitis occurs chiefly in newborns and debilitated elderly patients. The parotid gland is swollen, tender, and often erythematous, usually unilaterally. The diagnosis is made by expression of purulent material from Stensen duct. The material should be cultured. Fever and leukocytosis may be present. Treatment includes hospitalization and intravenous antibiotic therapy. *S. aureus* is the most common causative organism.

3. **Juvenile Recurrent Parotitis**

Some children experience recurrent nonsuppurative parotid inflammation with swelling or pain and fever. Juvenile recurrent parotitis (JRP) is most prevalent between the ages of 3 and 6 years, and it generally decreases by adolescence. The cause is unknown, but possible etiologic factors include ductal anomaly, autoimmune, allergy, and genetic. It usually occurs unilaterally. Treatment includes analgesics and some recommend an antistaphylococcal antibiotic for prophylaxis of bacterial infection and quicker resolution. Endoscopy of Stensen duct is being performed more frequently, not only to confirm diagnosis but also to provide treatment.

4. **Tumors of the Parotid Gland**

Mixed tumors, hemangiomas, sarcoidosis, and leukemia can manifest in the parotid gland as a hard or persistent mass. A cystic mass or multiple cystic masses may represent an HIV infection. Workup may require consultation with oncology, infectious disease, hematology, and otolaryngology.

5. **Ranula**

A ranula is a retention cyst of a sublingual salivary gland. It occurs on the floor of the mouth to one side of the lingual frenulum. It is thin walled and can appear bluish. Refer to an otolaryngologist for surgical management.

**CONGENITAL ORAL MALFORMATIONS**

1. **Tongue-Tie (Ankyloglossia)**

A short lingual frenulum can hinder both protrusion and elevation of the tongue. Puckering of the midline tongue tip is noted with tongue movement. Ankyloglossia can cause feeding difficulties in the neonate, speech problems, and dental problems. If the tongue cannot protrude past the teeth or alveolar ridge or move between the gums and cheek, referral to an otolaryngologist is indicated. A frenulectomy should be performed in the neonatal period if the infant is having difficulty breast-feeding. In our practice, neonatal frenulectomy is performed in clinic. Early treatment is favored, as when an infant is even several months old, general anesthesia is required for the procedure to be performed safely.

2. **Torus Palatini**

Torus palatini are hard, midline, palate masses which form at suture lines of the bone. They are usually asymptomatic and require no therapy, but they can be surgically reduced if necessary.

3. **Cleft Lip & Cleft Palate**

A. **Submucous Cleft Palate**

A bifid uvula is present in 3% of healthy children (see Chapter 37). However, a close association exists between bifid uvula and submucous cleft palate. A submucous cleft can be diagnosed by noting a translucent zone in the middle of the soft palate (zona pellucida). Palpation of the hard palate reveals absence of the posterior bony protrusion. Affected children have a 40% risk of developing persistent MEE. They are at risk for velopharyngeal incompetence, or an inability to close the palate against the posterior pharyngeal wall, resulting in hypernasal speech. During feeding, some of these infants experience nasal regurgitation of food. Children with submucous cleft palate causing abnormal speech or significant nasal regurgitation of food should be referred for possible surgical repair.

B. **High-Arched Palate**

A high-arched palate is usually a genetic trait of no consequence. It also occurs in children who are chronic mouth breathers and in premature infants who undergo prolonged oral intubation. Some rare causes of high-arched palate are congenital disorders such as Marfan syndrome, Treacher Collins syndrome, and Ehlers-Danlos syndrome.
Orthodontic treatment of a high arched palate can be an effective treatment for childhood OSA.

**C. Pierre Robin Sequence**

This group of congenital malformations is characterized by the triad of micrognathia, cleft palate, and glossoptosis. Affected children often present as emergencies in the newborn period because of infringement on the airway by the tongue and also because of feeding difficulties. The main objective of treatment is to prevent asphyxia until the mandible becomes large enough to accommodate the tongue.

In some cases, this can be achieved by leaving the child in a prone position when unattended. Other airway manipulations such as a nasal trumpet may be necessary. Distraction osteogenesis has been used to avoid tracheostomy. In severe cases, a tracheostomy is required. The child requires close observation and careful feeding until the problem is outgrown.

Respiratory Tract & Mediastinum

**Respiratory Tract**

Pediatric pulmonary diseases account for almost 50% of deaths in children younger than 1 year and about 20% of all hospitalizations of children younger than 15 years. Approximately 7% of children have a chronic disorder of the lower respiratory system. Understanding the pathophysiology of many pediatric pulmonary diseases requires an appreciation of the normal growth and development of the lung.

**Growth & Development**

The lung has its origins from an outpouching of the foregut during the fourth week of gestation. The development of the lung is divided into five overlapping stages.

1. **Embryonic stage** (3–7 weeks’ gestation): The primitive lung bud undergoes asymmetrical branching and then subsequent dichotomous branching, leading to the development of the conducting airways. It also involves the development of the large pulmonary arteries. Abnormalities during this stage result in congenital abnormalities such as lung aplasia, tracheoesophageal fistula, and congenital pulmonary cysts.

2. **Pseudoglandular stage** (5–17 weeks’ gestation): The conducting airways (bronchi and bronchioles) form over these 12 weeks. The respiratory epithelium of these airways begins to differentiate, and the presence of cartilage, smooth muscle cells, and mucus glands are first seen. In addition, the pleuroperitoneal cavity divides into two distinct compartments. Abnormalities during this stage lead to pulmonary sequestration, cystic adenomatoid malformation, and congenital diaphragmatic hernia.

3. **Canalicular stage** (16–26 weeks’ gestation): This stage witnesses the delineation of the pulmonary acinus. Type I alveolar cells appear; the pulmonary capillary network develops. Abnormalities of development during this stage include neonatal respiratory distress syndrome and lung hypoplasia.

4. **Saccular stage** (26–36 weeks’ gestation): Further branching of the terminal saccules takes place, as well as a thinning of the interstitium and fusion of the type I cells and capillary basement membrane in preparation for the lungs’ function as a gas-exchange organ. The beginning of an exponential increase in the epithelial surface area of gas exchange happens during the saccular stage.

5. **Alveolar stage** (36 weeks’ gestation to 3–8 years of age): Secondary alveolar septae form to increase the surface area for gas exchange, the capillary network has a rapid phase of growth, and true alveoli develop. New data suggest that postnatal alveolarization may continue for more than 7 years after birth.

At birth, the lung assumes the gas-exchanging function served by the placenta in utero, placing immediate stress on all components of the respiratory system. Any abnormality
in the lung, respiratory muscles, chest wall, airway, central respiratory control, or pulmonary circulation may lead to problems at birth. There is mounting evidence that disruption or abnormalities occurring during fetal and neonatal growth and development of the lung may have long-standing effects into adulthood, such as reduced gas exchange, exercise intolerance, asthma, pulmonary hypertension, and an increased risk of chronic obstructive pulmonary disease.

### DIAGNOSTIC AIDS

#### PHYSICAL EXAMINATION OF THE RESPIRATORY TRACT

The four components of a complete pulmonary examination include inspection, palpation, auscultation, and percussion.

**Inspection** of respiratory rate and work of breathing, is critical to the detection of pulmonary disease. In a study of children with respiratory illnesses, tachypnea, abnormalities of attentiveness, incontinence, respiratory effort, color, and movement had good diagnostic accuracy in detecting hypoxemia. **Palpation** of tracheal position, symmetry of chest wall movement, and vibration with vocalization can help in identifying intrathoracic abnormalities. For example, a shift in tracheal position can suggest pneumothorax or significant atelectasis. Tactile fremitus may change with consolidation or air in the pleural space. **Auscultation** should assess the quality of breath sounds and detect the presence of abnormal sounds such as fine or coarse crackles, wheezing, or rhonchi. Wheezing or prolonged expiratory compared to inspiratory time suggests intrathoracic airways obstruction.

Tachypnea with an equal inspiratory and expiratory time suggests decreased lung compliance. It is important to know the lung anatomy in order to identify the location of abnormal findings (Figure 19–1). In older patients, unilateral crackles are the most valuable examination finding in pneumonia. **Percussion** may identify tympanic or dull sounds that can help define an intrathoracic process. (This component of the examination can prove challenging in young children.)

Extrapulmonary manifestations of pulmonary disease include acute findings such as cyanosis and altered mental status and signs of chronic respiratory insufficiency such as growth failure, clubbing, and osteoarthropathy. Evidence of cor pulmonale (loud pulmonic component of the second heart sound, hepatomegaly, elevated neck veins, and rarely, peripheral edema) signifies pulmonary hypertension and may accompany advanced lung disease.

Respiratory disorders can be secondary to disease in other systems. It is therefore important to look for other conditions such as fever, metabolic acidosis, congenital heart disease, neuromuscular disease, immunodeficiency, autoimmune disease, and occult malignancy. Children with an elevated body mass index are more likely to present with respiratory symptoms and need to be evaluated for pulmonary pathology versus deconditioning or dyspnea.

#### PULMONARY FUNCTION TESTS

Pulmonary function tests (PFTs) are objective measures of lung and airway physiology that can help differentiate obstructive from restrictive lung diseases, measure...
disease progression, and evaluate response to therapy. Because the range of predicted normal values changes with growth, serial determinations of lung function are often more informative than a single determination. Patient cooperation and consistent effort is essential for almost all standard PFTs. Most children aged 8 and older can perform pulmonary function testing. Young children may be able to produce reliable results with coaching and visual incentives. Lung function measurements in infants and toddlers are available at centers with specialized equipment and expertise Children with cystic fibrosis (CF) and asthma should perform pulmonary function testing routinely as early as they can cooperate. Current spirometers use a pneumotachograph to record flow over time to produce a volume-time tracing (spirogram) or a flow-volume curve. The patient inhales maximally, holds his or her breath for a short period, and then exhales as fast and hard as possible until they reach residual volume or for at least 3 seconds. The values reported include: the forced vital capacity (FVC), which is the total volume of air that is exhaled; the forced expiratory volume in the first second of the exhalation (FEV1); the ratio of the FEV1/FVC; the forced expiratory flow at the middle of the vital capacity (FEF25–75); and the peak expiratory flow rate (PEFR). A suggested range of normal for these measurements are included in Table 19–1 and examples are shown in the figures. Obstructive processes include asthma, bronchopulmonary dysplasia (BPD), and CF. Restrictive lung disease can be caused by chest wall deformities that limit lung expansion, muscle weakness, and interstitial lung diseases (ILDs). Confirmation of restrictive lung or chest wall physiology requires lung volume measurements (eg, total lung capacity, residual volume, and functional residual capacity) because poor test performance or effort can mimic restrictive physiology. Lung volume measurements require special equipment. (For examples of PFTs, see Figures 19–2, 19–3, and 19–4.)

The PEFR, the maximal flow recorded during an FVC maneuver, can be assessed by handheld devices. These devices are not as well calibrated as spirometers and the PEFR measurement can vary greatly with patient effort, so they are not good substitutes for actual spirometry. However, peak flow monitoring can be helpful in a patient with asthma that is difficult to control or for patients with poor perception of their airflow obstruction.

Seed L, Wilson D, Coates AL: Children should not be treated like little adults in the PFT lab. Respir Care 2012;57(1):61–74 [PMID: 22222126].

### ASSESSMENT OF OXYGENATION & VENTILATION

Arterial blood gas measurements define the acid-base balance between respiration at the tissue level and in the lungs. Blood gas measurements evaluate hypoxemia, acidosis, and hypercarbia and can be used to categorize acid-base disturbances as respiratory, metabolic, or mixed. Blood gas measurements are affected by abnormalities of respiratory control, gas exchange, respiratory mechanics, and the circulation. In pediatrics, hypoxemia (low partial pressure of arterial oxygen [Pao2]) most commonly results from ventilation (V) and perfusion (Q) mismatch. Common pediatric diseases that may be associated with hypoxemia due to V/Q mismatch include acute asthma, CF, pneumonia, bronchiolitis, and BPD. Other causes of hypoxemia include hypoventilation, shunts, and diffusion barrier for oxygen. Hypercapnia (elevated partial pressure of arterial carbon dioxide [Paco2]) results from inadequate alveolar ventilation or hyperventilation (ie, inability to clear the CO2 produced). Causes include decreased central respiratory drive, respiratory muscle weakness, and low-tidal-volume breathing as seen in restrictive lung or chest wall diseases. Hypercapnea can also occur when severe V/Q mismatch is present which may occur with severe CF or BPD. Table 19–2 gives normal values for arterial pH, Pao2, and Paco2 at sea level and at 5000 ft.

| Table 19–1. Classification of lung function abnormalities. |
|---------------------------------|---------------------------------|---------------------------------|
| **Range of Normal**             | **Type of Lung Disease**        |                                 |
| FVC (L)                         | Obstructivea                   | Normal or decreased             |
| FEV1 (L)                        | Restrictiveb                   | Decreased                      |
| FEV1/FVC ratio                  |                                 | Decreased                      |
| FEF25–75 (L/sec)                |                                 | Decreased or increased or decreased |

FEF25–75, forced expiratory flow at 25%–75% of FVC; FEV1, forced expiratory volume in the first second of exhalation; FVC, forced vital capacity.
Venous blood gas analysis or capillary blood gas analysis can be useful for the assessment of Pco₂ and pH, but not Po₂ or saturation. Noninvasive assessment of oxygenation can be achieved with pulse oximetry (measuring light absorption by transilluminating the skin). Oxygenated hemoglobin absorbs light at different wavelengths than deoxygenated hemoglobin. Measurement during a systolic pulse allows estimation of arterial oxygen saturation. Values of oxygen saturation are reliable as low as 80%. Reliability is reduced with poor arterial pulsation (eg, with hypothermia, hypotension, or infusion of vasoconstriction). Carbon monoxide bound to hemoglobin results in falsely high oxygen saturation readings. Exhaled or end-tidal CO₂ monitoring can be used to noninvasively estimate arterial CO₂ content. It is used to monitor alveolar ventilation and is most accurate in patients without significant lung disease, particularly those good V/Q matching and without airway obstruction. Monitoring of exhaled or end-tidal CO₂ is commonly used during polysomnography and anesthesia. Transcutaneous Pco₂ monitoring is also feasible but may be less reliable than transcutaneous Po₂ monitoring and should be used with caution.

**DIAGNOSIS OF RESPIRATORY TRACT INFECTIONS**

Respiratory tract infections may be caused by bacteria, viruses, atypical bacteria (eg, *Mycoplasma pneumonia* and *Chlamydia pneumoniae*), *Mycobacterium tuberculosis*,...
nontuberculous mycobacterium, or fungi (eg, *Aspergillus* and *Pneumocystis jiroveci*). The type of infection suspected and appropriate diagnostic tests vary depending on factors such as underlying lung disease, immune function, and geographic region. Sources of respiratory tract secretions for diagnostic testing include nasopharyngeal and oropharyngeal swabs; expectorated and induced sputum; tracheal aspirates; direct lung or pleural fluid sampling; BAL fluid; and gastric aspirates, specifically for *M tuberculosis*.

Spontaneously expectorated sputum is the least invasive way to collect a sample for diagnostics, though it is rarely available from patients younger than 6 years. Sputum induction, performed by inhaling aerosolized hypertonic saline, is a relatively safe, noninvasive means of obtaining lower airway secretions. Sputum induction has been used in patients with CF and may be useful in patients with suspected *M tuberculosis*, *P jiroveci* pneumonia, or complicated community-acquired pneumonia. Tracheal aspirates can be obtained easily from patients with endotracheal or tracheostomy tubes. Culture of respiratory tract samples is the most commonly used approach to detect and identify airway pathogens. Molecular diagnostic tests, based on PCR amplification and detection of nucleic acid from microbes, are often more rapid and sensitive, and may be used for detection of typical bacterial pathogens (eg, *Streptococcus pneumoniae*, *Methicillin-resistant Staphylococcus aureus*), as well as detection of *M tuberculosis*, *P jiroveci*, and fastidious bacteria such as anaerobes. Blood and urine samples also may be used for serologic and antigen testing.

▲ *Figure 19-3.* Flow volume loops from a child with asthma (obstructive pattern with bronchodilator response).
IMAGING OF THE RESPIRATORY TRACT

The plain chest radiograph remains the foundation for investigating the pediatric thorax. Both frontal (posterior-anterior) and lateral views should be obtained if feasible. The radiograph is useful for evaluating chest wall abnormalities, heart size and shape, mediastinum, diaphragm, and lung parenchyma. When pleural fluid is suspected, lateral decubitus radiographs may be helpful in determining the extent and mobility of the fluid. When a foreign body is suspected, forced expiratory radiographs may show focal air trapping and shift of the mediastinum to the contralateral side. Lateral neck radiographs can be useful in assessing the size of adenoids and tonsils and also in differentiating croup from epiglottitis, the latter being associated with the “thumbprint” sign.

Fluoroscopic studies including upper gastrointestinal series or videofluoroscopic swallowing studies are indicated for detection of swallowing dysfunction in patients with suspected aspiration, tracheoesophageal fistula, vascular rings and slings, and achalasia. Fluoroscopy or ultrasound of the diaphragm can detect paralysis by demonstrating paradoxical movement of the involved hemidiaphragm.

Chest CT is useful in evaluation of congenital lung lesions, pleural disease (eg, effusion or recurrent pneumothorax), mediastinum (eg, lymphadenopathy), pulmonary nodules or masses. High-resolution CT is best for evaluating ILD or bronchiectasis while decreasing radiation exposure compared to a standard CT. Magnetic resonance imaging (MRI) is useful for defining vascular or bronchial anatomical

abnormalities. Ventilation-perfusion scans can provide information about regional ventilation and perfusion and can help detect vascular malformations and pulmonary emboli. Pulmonary angiography is occasionally necessary to define the pulmonary vascular bed more precisely. Concerns about radiation exposure in children led to the Image Gently campaign, an initiative of The Alliance for Radiation Safety in Pediatric Imaging, dedicated to increasing awareness of the need for radiation protection for children. Identified challenges include the need for continued education particularly at adult-focused hospitals, increased emphasis on appropriateness of pediatric imaging and outcomes research to validate the use of CT, and establishing ranges of optimal CT technique when imaging children.

**LARYNGOSCOPY & BRONCHOSCOPY**

Direct visualization of the airways may be necessary for diagnosis despite an extensive history and physical and sophisticated imaging. This can be achieved with rigid or flexible instrumentation. Indications for laryngoscopy include hoarseness, stridor, symptoms of obstructive sleep apnea, and laryngeal wheezing. Indications for bronchoscopy include wheezing, suspected foreign body, recurrent pneumonia, persistent atelectasis, chronic cough, and hemoptysis. A flexible bronchoscope can also be used to assess placement and patency of an endotracheal tube. In general, the more specific the indication, the higher the diagnostic yield. Each method, rigid or flexible, has advantages and for some patients both should be employed sequentially under the same anesthesia.

The rigid, open tube instruments have the best optics and allow surgical intervention to be easily achieved, such as removal of a foreign body. Rigid bronchoscopy is done with general anesthesia. Flexible laryngoscopy may be done with topical anesthesia or light sedation and flexible bronchoscopy can be done with either conscious sedation or general anesthesia. The flexible bronchoscope is of a smaller caliber and allows more distal examination of airways. Because it is smaller, the flexible bronchoscope does not stent the airway open during the procedure and often dynamic airway collapse is more easily documented by the flexible procedure. BAL is useful to sample the alveolar space for infection, inflammation, hemorrhage, or aspiration. Although removal of foreign bodies has been achieved with the flexible bronchoscope in larger children, the standard of care in most institutions is to remove foreign bodies via the rigid bronchoscope.

Transbronchial biopsy in children is limited to evaluation of infection and rejection in lung transplant patients. There is low diagnostic yield in most other conditions. Transbronchial biopsy may have a role in sarcoidosis. Video-assisted thoracoscopic lung biopsy (VATS) provides a more substantial specimen for pathologic assessment.

**GENERAL THERAPY FOR PEDIATRIC LUNG DISEASES**

**OXYGEN THERAPY**

Physical findings of hypoxemia are subtle. Adequate oxygenation should be measured by the arterial oxygen tension or pulse oximetry. The advantages of the latter noninvasive method include the ability to obtain continuous measurements during normal activities and to avoid artifacts caused by crying or breath-holding during arterial puncture. For children with cardiopulmonary disorders that require chronic supplemental oxygen therapy (eg, BPD or CF), frequent noninvasive assessments are essential to ensure the safety and adequacy of O2 treatment.

The goal of supplemental oxygen (O2) therapy is to relieve hypoxemia. Supplemental oxygen can reduce the work of breathing, resulting in fewer respiratory symptoms; relax the pulmonary vasculature, lessening the potential for pulmonary hypertension and congestive heart failure; and improve feeding. Patients breathing spontaneously can be treated by nasal cannula, head hood, or mask (including simple, rebreathing, nonrebreathing, or Venturi masks). The goal of O2 therapy is to achieve an arterial oxygen tension of 65–90 mm Hg or oxygen saturation above 90%, although lower Pao2 or SpO2 levels may be acceptable in certain situations. The actual O2 concentration achieved by nasal cannula or mask depends on the flow rate, the type of mask used, and the patient’s age. Small changes in flow rate during oxygen administration by nasal cannula can lead to substantial changes in inspired oxygen concentration in young infants. The amount of oxygen required to correct hypoxemia may vary according to activity. It is not unusual, for example, for an infant with chronic lung disease to require 0.75 L/min while awake but 1 L/min while asleep or feeding.

Although the head hood is an efficient device for delivery of oxygen in young infants, the nasal cannula is used more often because it allows greater mobility. The nasal cannula has nasal prongs that are inserted in the nares. Even at high flow rates, oxygen by nasal cannula rarely delivers inspired oxygen concentrations greater than 40%–45%.
In contrast, partial rebreathing and nonrebreathing masks or head hoods achieve inspired oxygen concentrations as high as 90%–100%. Heated high-flow nasal cannulas have been developed recently to deliver a high flow rate. The data supporting heated high-flow oxygen in children are variable. There is also no definitive evidence that heated high-flow can be used as a form of noninvasive ventilation in children.

INHALATION OF MEDICATIONS

Inhalation of medications is a mainstay of therapy for pediatric respiratory conditions and are routinely used in patients with chronic diseases such as CF, BPD, and asthma, as well as in acute illnesses such as infectious laryngotracheobronchitis and bronchiolitis (Table 19–3). Short-acting β-agonists and anticholinergics provide acute bronchodilatation (relievers), whereas inhaled corticosteroids and cromones provide anti-inflammatory effects (controllers). Nebulized antibiotics have documented benefit in CF and nebulized mucolytic medications (eg, rhDNAse and hypertonic saline) are used in CF and other conditions with impaired secretion control such as non-CF bronchiectasis.

The medications can be delivered by pressurized metered dose inhaler (pMDI), dry powder inhaler (DPI), or compressed air-driven wet nebulization. Careful attention to delivery technique is critical to optimize medication delivery to the airways. A valved holding chamber or similar spacer should be used with pMDI use, and this technique has been shown to be effective in infants as young as 4 months of age. A face-mask interface is recommended for both pMDI and wet nebulization in infants and toddlers; a simple mouth piece suffices for older children who can form a seal around the mouthpiece. Delivery technique should be assessed and reviewed at each clinical visit.

AIRWAY CLEARANCE THERAPY

Chest physical therapy, with postural drainage, percussion, and forced expiratory maneuvers, has been widely used to improve the clearance of lower airway secretions in children with CF, bronchiectasis, and neuromuscular disorders. Currently available airway clearance techniques include: chest physiotherapy, autogenic drainage, blowing therapies (bubbles, pinwheels), active coughing, positive expiratory

pressure (PEP) with handheld devices, intrapulmonary percussive ventilation and high-frequency chest compression. The decision about which technique to use should be based on the patient’s age and preference after trying different approaches. Daily exercise is an important adjunctive therapy for airway clearance and overall lung health. Cough assist devices (eg, mechanical insufflator-exsufflators) are useful for children with a weak cough due to neuromuscular disorders such as muscular dystrophy and spinal muscular atrophy. Bronchodilators or mucolytic medications may be given prior to or during airway clearance therapy. If prescribed, inhaled corticosteroids and inhaled antibiotics should be given after airway clearance therapy so that the airways are first cleared of secretions, allowing the medications to maximally penetrate the lung. Airway clearance has not been shown to be beneficial for patients with acute respiratory illnesses such as pneumonia, bronchiolitis, and asthma.

AVOIDANCE OF ENVIRONMENTAL HAZARDS

Environmental insults can aggravate existing lung diseases and impair pulmonary function, and cause lung disease in children. Outdoor air pollution (ozone and particulates), indoor pollution, diesel exhaust, and household fungi are examples. Environmental tobacco smoke dramatically increases childhood pulmonary morbidity. Smoking family members should be counseled to quit smoking and do everything possible to minimize environmental smoke exposure to the people around them. Homes with mold should have remediation, particularly if children with lung disease are in residence. Ozone exposure can be limited by avoiding outdoor activities during the height of daily ozone levels.

For children with asthma, family pets may be a significant trigger as can household cockroach infestation. Despite the known risk, many families are reluctant to eliminate the risk of exposure to the pet.

DISORDERS OF THE CONDUCTING AIRWAYS

The conducting airways include the nose, mouth, pharynx, larynx, trachea, bronchi, and terminal bronchioles. These airways direct inspired air to the gas-exchange units of the lung but do not participate in gas exchange. Airflow obstruction in the conducting airways can occur at extrathoracic sites (eg, above the thoracic inlet) or at intrathoracic sites (eg, below the thoracic inlet). Extrathoracic or upper airway obstruction disrupts the inspiratory phase of respiration and is often manifest by stridor or “noisy breathing.” Intrathoracic obstruction disrupts the expiratory phase of respiration and is often manifest by wheezing and prolongation of the expiratory phase. After assessing whether the obstruction is extrathoracic or intrathoracic the next challenge is to determine if the obstruction is fixed or variable. Fixed obstructions disrupt each breath and the abnormal sounds are consistently heard. Fixed obstructions can be intrinsic to the airway or due to airway compression (extrinsic). They are often associated with anatomic abnormalities that may be amenable to surgical correction (Table 19–4).

Variable obstruction leads to abnormal sounds with breathing that are softer or absent with normal quiet breathing and may sound different with every breath. Variable obstructions are often due to dynamic changes in airway caliber that occurs with laryngomalacia, tracheomalacia, or bronchomalacia. The onset and progression of the obstruction can

provide important clues as to the etiology and help determine the urgency of evaluation and management. Obstructions due to dynamic airway collapse often improve with age, whereas fixed obstructions typically progress or fail to improve with age. Acute onset extrathoracic obstruction is often infectious. Clinical indications that the obstruction is severe include high-pitched stridor or wheezing, biphasic stridor, drooling or dysphagia, poor-intensity breath sounds, severe retractions, and poor color or cyanosis.

Helpful diagnostic studies in the evaluation of extrathoracic obstruction include chest and lateral neck radiographs, airway fluoroscopy, and barium swallow. Patients who have symptoms of severe chronic obstruction should have an electrocardiogram and/or ECHO to evaluate for right ventricular hypertrophy and pulmonary hypertension. Patients suspected to have obstructive sleep apnea should have polysomnography (see section Sleep-Disordered Breathing). Diagnostic studies for intrathoracic obstruction include two-view chest radiographs, a sweat test, and PFTs. Other diagnostic studies are dictated by the history and physical findings. If asthma is suspected, a trial of bronchodilators and/or anti-inflammatories should be considered. If noninvasive studies are unable to establish the cause of airway obstruction, laryngoscopy and bronchoscopy are indicated to establish the diagnosis. In older children, PFTs can differentiate fixed from variable airflow obstruction and may identify the site of obstruction. Treatment should be directed at relieving airway obstruction and correcting the underlying condition if possible.

**LARYNGOMALACIA & CONGENITAL DISORDERS OF THE EXTRATHORACIC AIRWAY**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Presentation from birth or within the first few weeks of life.
- Intermittent, high-pitched, inspiratory stridor.
- Moderate to severe symptoms require visualization of the airway.

**LARYNGOMALACIA**

Laryngomalacia is a benign congenital disorder in which the cartilaginous support for the supraglottic structures is underdeveloped. It is the most common cause of variable extrathoracic airway obstruction and manifests as intermittent stridor in infants, usually within the first 6 weeks of life. Stridor is generally worse in the supine position, with increased activity, with upper respiratory infections, and during feeding; however, the clinical presentation can be variable. The condition usually improves with age and resolves by the time the child is 2 years old, but can persist for years. The diagnosis is established by laryngoscopy, which shows inspiratory collapse of an omega-shaped epiglottis (with or without long, redundant arytenoids). In mildly affected patients with no stridor at rest and no retractions, treatment is not usually needed. Patients with either severe symptoms of airway obstruction such as stridor with each breath, retractions, and increased work of breathing or more chronic signs such as feeding difficulties, failure to thrive, obstructive sleep apnea, hypoxemia, or severe dyspnea may benefit from surgical epiglottoplasty.

**OTHER CAUSES OF CONGENITAL EXTRATHORACIC OBSTRUCTION**

Other congenital lesions of the larynx such as laryngeal atresia, laryngeal web, laryngocele and cyst of the larynx, subglottic hemangioma, laryngeal cleft, and subglottic stenosis usually present as fixed extrathoracic obstruction and are best evaluated by direct laryngoscopy.

- Laryngeal atresia presents at birth with severe respiratory distress and is often fatal.
- Laryngeal web, representing fusion of the anterior portion of the true vocal cords, is associated with hoarseness, aphonia, and stridor at birth and requires immediate intervention.
- Laryngeal cysts and laryngoceles present with stridor and significant airway obstruction. Laryngeal cysts are superficial and are generally fluid filled. Laryngoceles communicate with the interior of the larynx and may be either air- or fluid-filled. Both require surgery or laser therapy.
- Subglottic hemangiomas are a rare cause of upper airway obstruction in infants and are associated with cutaneous vascular lesions of the skin in 50%–60% of patients. Although vascular malformations regress spontaneously, airway obstruction requires intervention. Medical management options include propranolol, systemic steroids, or intralesional steroids. Surgical intervention with laser ablation is usually successful. Tracheostomy is rarely required.
- Laryngeal cleft is an uncommon condition resulting from failure of posterior cricoid fusion. Patients present with

Subglottic stenosis can be congenital or acquired. Paralysis or subglottic stenosis.

The differential for acquired disorders includes aspiration due to foreign body ingestion; however, rigid bronchoscopy is the gold standard for diagnosis. Acquired disorders of the extrathoracic airway present with inspiratory sounds consistent with stridor. The pitch of the sound varies depending on the diagnosis. Upper airway obstruction can progress quickly and may be life-threatening, requiring close observation. The differential for acquired disorders includes aspiration, infection, and injury or trauma leading to vocal cord paralysis or subglottic stenosis.

FOREIGN BODY ASPIRATION IN THE EXTRATHORACIC AIRWAY

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Sudden onset of coughing or respiratory distress.
- Difficulty vocalizing.

Aspiration of a foreign body into the respiratory tract is a significant cause of accidental death each year. The foreign body can lodge anywhere along the respiratory tract. Foreign bodies that lodge in the esophagus may compress the airway and cause respiratory distress. More typically, the foreign body lodges in the supraglottic airway, triggering protective reflexes that result in laryngospasm. Small objects such as coins may pass through the glottis and obstruct the trachea. Objects that pass into the lower airway cause coughing and more variable respiratory distress (see section Acquired Causes of Intrathoracic Airway Obstruction).

Foreign body aspiration is commonly seen with small, round foods such as nuts and seeds, berries, corn/popcorn, hot dogs, and beans. Children 6 months to 3 years are at the highest risk. Homes and child care centers in which an older sibling or child feeds age-inappropriate foods (eg, peanuts, hard candy, or carrot slices) to the younger child are typical. Without treatment, progressive cyanosis, loss of consciousness, seizures, bradycardia, and cardiopulmonary arrest can follow.

Clinical Findings

Signs at the time of aspiration can include coughing, choking, or wheezing. Onset is generally abrupt, with a history of the child running with food in the mouth or playing with seeds, small coins, or toys.

The diagnosis is established by acute onset of choking along with inability to vocalize or cough and cyanosis with marked distress (complete obstruction), or with drooling, stridor, and ability to vocalize (partial obstruction). Chest x-rays and other imaging studies have been used to evaluate for foreign body ingestion; however, rigid bronchoscopy is the gold standard for diagnosis.

Treatment

Prevention is paramount. Pediatricians should counsel caregivers regarding age-specific safe foods. Small toys and latex balloons should have age-appropriate choking warnings on their labels. In the event of acute upper airway obstruction due to foreign body aspiration, emergency treatment depends on the amount of obstruction. If partial obstruction is present, then the choking subject should be allowed to use his or her own cough reflex to remove the foreign body. If the obstruction increases or the airway is completely obstructed, acute intervention is required. An awake child younger than 1 year with a complete obstruction should be placed face down over the rescuer’s arm. Five measured back blows are delivered rapidly followed by rolling the infant over and delivering five rapid chest thrusts. This sequence is repeated until the obstruction is relieved. In a choking child older than 1 year, abdominal thrusts (Heimlich maneuver) should be performed. If the child of any age becomes unresponsive, cardiopulmonary resuscitation is recommended. Chest compressions may help to dislodge the foreign body.

Blind finger sweeps should not be performed in infants or children because the finger may push the foreign body...
further into the airway. The airway should be opened by jaw thrust, and if the foreign body can be directly visualized, careful removal with the fingers or instruments should be attempted. Patients with persistent apnea and inability to achieve adequate ventilation may require emergency intubation, tracheotomy, or needle cricothyrotomy, depending on the setting and the rescuer’s skills. Foreign body removal is most successfully performed using rigid bronchoscope under general anesthesia.

CROUP SYNDROMES

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► New onset stridor in the setting of an upper respiratory illness or fever.

Croup describes acute inflammatory diseases of the larynx, including viral croup (laryngotracheobronchitis), epiglottitis (supraglottitis), and bacterial tracheitis. These are the main entities in the differential diagnosis for patients presenting with acute stridor, although spasmodic croup, angioedema, laryngeal or esophageal foreign body, and retropharyngeal or peritonsillar abscess should be considered as well.

1. Viral croup

Viral croup generally affects young children 6 months to 5 years of age in the fall and early winter and is most often caused by parainfluenza virus serotypes. However, many other viral organisms as well as M pneumoniae can cause croup. Edema in the subglottic space accounts for the predominant signs of upper airway obstruction although inflammation of the entire airway is often present.

► Clinical Findings

A. Symptoms and Signs

Usually, a prodrome of upper respiratory tract symptoms is followed by a barking cough and stridor. Fever is usually absent. Patients with mild disease may have stridor when agitated. As obstruction worsens, stridor occurs at rest, accompanied in severe cases by retractions, air hunger, and cyanosis. On examination, the presence of cough and the absence of drooling favor the diagnosis of viral croup over epiglottitis.

B. Imaging

Anteroposterior and lateral neck radiographs are not routinely indicated for patients with classic presentation of croup. For atypical presentation, x-ray shows subglottic narrowing (the steeple sign) without the irregularities seen in tracheitis and a normal epiglottis. A severely ill patient should never be left unattended in the imaging suite.

► Treatment

Treatment of viral croup is based on the symptoms. Mild croup, signified by a barking cough and no stridor at rest, requires supportive therapy with oral hydration and minimal handling. Mist therapy has historically been used but clinical studies do not demonstrate effectiveness. Conversely, patients with stridor at rest require active intervention. Oxygen should be administered to patients with oxygen desaturation. Nebulized racemic epinephrine (0.5 mL of 2.25% solution diluted in sterile saline) is commonly used because it has a rapid onset of action within 10–30 minutes. Both racemic epinephrine and epinephrine hydrochloride (l-epinephrine, an isomer) are effective in alleviating symptoms and decreasing the need for intubation.

The efficacy of glucocorticoids in croup is now firmly established. Dexamethasone, 0.6 mg/kg intramuscularly as one dose, improves symptoms, reduces the duration of hospitalizations and frequency of intubations, and permits earlier discharge from the emergency department. Oral dexamethasone (0.15 mg/kg) may be equally effective for mild to moderate croup. Inhaled budesonide (2–4 mg) also improves symptoms and decreases hospital stay and may be as effective as dexamethasone. Dexamethasone has also been shown to be more effective than prednisolone in equivalent doses. The use of heliox, a mixture of helium and oxygen, improves turbulent airflow, but is not superior to nebulized medication. Its use is limited in hypoxic children because of its low fractional concentration of inspired oxygen.

If symptoms resolve within 3–4 hours of glucocorticoids and nebulized epinephrine, patients can safely be discharged without fear of a sudden rebound in symptoms. If, however, recurrent nebulized epinephrine treatments are required or if respiratory distress persists, patients require hospitalization for close observation, supportive care, and nebulization treatments as needed. In patients with impending respiratory failure, an airway must be established. Intubation with an endotracheal tube of slightly smaller diameter than would ordinarily be used is reasonably safe. Extubation should be accomplished within 2–3 days to minimize the risk of laryngeal injury. Other underlying causes should be considered in hospitalized patients with persistent symptoms over 3–4 days despite treatment.
Prognosis
Most children with viral croup have an uneventful course and improve within a few days. Some evidence suggests that patients with a history of croup associated with wheezing may have airway hyperreactivity. It is not always clear if the hyperreactivity was present prior to the croup episode or if the viral infection causing croup altered airway function.

2. Epiglottitis
With the introduction of the *Haemophilus influenzae* conjugate vaccine, the incidence of epiglottitis is rare in countries with immunization programs. If disease occurs, it is likely to be associated with *H influenzae* in unimmunized children, or another organism such as nontypeable *H influenzae*, *Neisseria meningitidis*, or *Streptococcus* species in immunized populations.

Clinical Findings
A. Symptoms and Signs
The classic presentation is a sudden onset of high fever, dysphagia, drooling, muffled voice, inspiratory retractions, cyanosis, and soft stridor. Patients often sit in the so-called sniffing dog position, with the neck hyperextended and the chin stretched forward, which gives them the best airway possible under the circumstances. Progression to total airway obstruction may occur and result in respiratory arrest. The definitive diagnosis is made by direct inspection of the epiglottis, a procedure that should be done by an experienced airway specialist under controlled conditions (typically in the operating room during intubation). The typical findings are a cherry-red and swollen epiglottis and swollen arytenoids.

B. Imaging
Diagnostically, lateral neck radiographs may be helpful in demonstrating a classic “thumbprint” sign caused by the swollen epiglottis. Obtaining radiographs, however, may delay important airway intervention.

Treatment
Once the diagnosis of epiglottitis is made, endotracheal intubation must be performed immediately in children but not necessarily in adults. Most anesthesiologists prefer general anesthesia (but not muscle relaxants) to facilitate intubation. After an airway is established, cultures of the blood and epiglottis should be obtained and the patient should be started on appropriate intravenous antibiotics to cover *H influenzae* and *Streptococcus* species (ceftriaxone sodium or an equivalent cephalosporin). Extubation can usually be accomplished in 24–48 hours, when direct inspection shows a significant reduction in the size of the epiglottis. Intravenous antibiotics should be continued for 2–3 days, followed by oral antibiotics to complete a 10-day course.

Prognosis
Prompt recognition and appropriate treatment usually results in rapid resolution of swelling and inflammation. Recurrence is unusual.

3. Bacterial Tracheitis
Bacterial tracheitis (pseudomembranous croup) is a severe life-threatening form of laryngotracheobronchitis. As the management of severe viral croup has been improved with the use of dexamethasone, and vaccination has decreased the incidence of epiglottitis, tracheitis is relatively more common as a cause of a pediatric airway emergency requiring admission to the pediatric intensive care unit. This diagnosis must be high in the differential when a patient presents with severe upper airway obstruction and fever. The organism most often isolated is *Staphylococcus aureus*, but organisms such as *H influenzae*, group A *Streptococcus pyogenes*, *Neisseria* species, *Moraxella catarrhalis*, and others have been reported. A viral prodrome is common. Viral coinfections are described and influenza should be treated. The disease probably represents localized mucosal invasion of bacteria in patients with primary viral croup, resulting in inflammatory edema, purulent secretions, and pseudomembranes. Although cultures of the tracheal secretions are frequently positive, blood cultures are almost always negative.

Clinical Findings
A. Symptoms and Signs
The early clinical picture is similar to that of viral croup. However, instead of gradual improvement, patients develop higher fever, toxicity, and progressive or intermittent severe
upper airway obstruction that is unresponsive to standard croup therapy. The incidence of sudden respiratory arrest or progressive respiratory failure is high, requiring airway intervention. Findings of toxic shock and the acute respiratory distress syndrome may also be seen. Aggressive medical treatment and debridement is indicated.

B. Laboratory Findings and Imaging
The white cell count is usually elevated with a left shift. Cultures of tracheal secretions usually demonstrate one of the causative organisms. Lateral neck radiographs show a normal epiglottis but severe subglottic and tracheal narrowing. Irregularity of the contour of the proximal tracheal mucosa can frequently be seen radiographically and should elicit concern for tracheitis. Bronchoscopy showing a normal epiglottis and the presence of copious purulent tracheal secretions and membranes confirms the diagnosis.

▶ Treatment
Patients with suspected bacterial tracheitis will require direct visualization of the airway in a controlled environment and debridement of the airway. Most patients will be intubated because the incidence of respiratory arrest or progressive respiratory failure is high. Patients may also require further debridement, humidification, frequent suctioning, and intensive care monitoring to prevent endotracheal tube obstruction by purulent tracheal secretions. Intravenous antibiotics to cover *S. aureus*, *H. influenzae*, and the other organisms are indicated. Thick secretions persist for several days, usually resulting in longer periods of intubation for bacterial tracheitis than for epiglottitis or croup. Despite the severity of this illness, the reported mortality rate is very low if it is recognized and treated promptly.

VOCAL FOLD IMMOBILITY

▶ Hoarseness or stridor.
▶ May present with difficulty swallowing.

SUBGLOTTIC STENOSIS

▶ Chronic or recurrent stridor.
▶ History of airway trauma is common in acquired subglottic stenosis.

Subglottic stenosis may be congenital, or more commonly may result from endotracheal intubation. Neonates and infants are particularly vulnerable to subglottic injury from intubation. The subglottis is the narrowest part of an infant’s airway, and the cricoid cartilage, which supports the subglottis, is the only cartilage that completely encircles the airway. This area is therefore susceptible to injury when an
endotracheal tube is inserted. The clinical presentation may vary from asymptomatic to severe upper airway obstruction. Subglottic stenosis should be suspected in children who repeatedly fail extubation or children with multiple, prolonged, or severe episodes of croup. Diagnosis is made by direct visualization of the subglottic space with bronchoscopy and maneuvers to size the airway. Tracheostomy is often required when airway compromise is severe. Laryngotracheal reconstruction, in which a cartilage graft from another source (eg, rib) is used to expand the airway, has become the standard procedure for severe subglottic stenosis in children. In mild cases, balloon dilation of the subglottis is a less invasive alternative.

CONGENITAL CAUSES OF INTRATHORACIC AIRWAY OBSTRUCTION

Congenital disorders of intrathoracic airway obstruction airway can present acutely or with recurrent symptoms of lower airway obstruction. Children with disorders of the intrathoracic airway often present with expiratory sounds such as wheeze, recurrent cough, and/or recurrent pneumonia due to retained secretions. The differential for intrathoracic airway obstruction includes airway malacia, extrinsic compression (eg, vascular ring), and congenital anomalies such as bronchogenic cysts.

MALACIA OF AIRWAYS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Chronic monophonic wheeze with or without a barking cough.
- Respiratory symptoms do not respond to bronchodilators.

Pathogenesis

Tracheomalacia or bronchomalacia exists when the cartilaginous framework of the airway is inadequate to maintain airway patency. Airway collapse is dynamic and can lead to airway obstruction. Because infant airway cartilage is normally soft, infants have some degree of dynamic collapse of the central airway during the phases of respiration. Tracheomalacia and bronchomalacia can be congenital or acquired. Congenital tracheomalacia and bronchomalacia are associated with developmental abnormalities such as tracheoesophageal fistula, vascular ring, or cardiac anomalies causing extrinsic airway compression during development. Congenital tracheomalacia may be localized or diffuse and may extend through to the remainder of the conducting airways (bronchomalacia). Acquired tracheomalacia has been associated with long-term ventilation of preterm infants due to delayed cartilaginous development with or without direct positive pressure, severe tracheobronchitis, surgical repair of airways anomalies such as tracheoesophageal fistula and complete tracheal rings, and extrinsic airway compression due to tumors, abscess or infection, cysts, and compression during development such seen in congenital heart disease with associated ventricular hypertrophy or vascular anomalies.

Clinical Findings

Coarse and recurrent wheezing, cough, or stridor that do not respond to bronchodilators are common findings. Preterm infants with trachea or bronchomalacia may require positive pressure ventilation or continuous nasal cannula oxygen to maintain oxygenation. Symptoms classically present insidiously over the first few months of life and can increase with agitation, excitement, activity, or upper respiratory tract infections. Diagnosis can be made by airway fluoroscopy or bronchoscopy.

Treatment

Observation is usually indicated for mild symptoms, which generally improve over time with growth. Coexisting lesions such as tracheoesophageal fistulas and vascular rings need primary repair. In severe cases of tracheomalacia, intubation or tracheostomy may be necessary. Unfortunately, tracheostomy alone is seldom satisfactory because airway collapse continues to exist below the tip of the artificial airway. Positive pressure ventilation may be required to stent the airway open. Surgical intervention (tracheopexy, aortopexy, or stents) may be considered for the most challenging situations.

Prognosis

The resolution of symptoms due to airway malacia depends upon the severity and extent of the airway malacia and any underlying illness in the child. Children with mild malacia who do not have other underlying lung disease or neuromuscular disease will most likely have at least partial resolution by the time they are 3–4 years old.

The most common vascular anomaly to compress the trachea or esophagus is a vascular ring. A vascular ring can be formed by a double aortic arch or a right aortic arch with left ligamentum arteriosum or a patent ductus arteriosus. The pulmonary sling is created when the left pulmonary artery branches off the right pulmonary artery. Other common vascular anomalies include an anomalous innominate artery, a left carotid artery, and an aberrant right subclavian artery. All but the right subclavian artery can cause tracheal compression. The pulmonary sling may compress the trachea but can also compress the right upper lobe bronchus or the right mainstem takeoff. A pulmonary sling is associated with long segment tracheal stenosis 50% of the time.

Clinical Findings
A. Symptoms and Signs
Symptoms of chronic airway obstruction (stridor, coarse wheezing, and croupy cough) are often worse in the supine position. Respiratory compromise is most severe with double aortic arch and may lead to apnea, respiratory arrest, or even death. Esophageal compression may result in feeding difficulties. Barium swallow showing esophageal compression is the mainstay of diagnosis in all but anomalous innominate or carotid artery. Chest radiographs and echocardiograms may miss abnormalities. Anatomy can be further defined by angiography, chest CT with contrast, MRI or magnetic resonance angiography, or bronchoscopy.

Treatment
Patients with significant symptoms require surgical correction, especially those with double aortic arch. Patients usually improve following correction but may have persistent but milder symptoms of airway obstruction due to associated tracheomalacia.

Bronchogenic cysts generally occur in the middle mediastinum (see section Mediastinal Masses) near the carina and adjacent to the major bronchi but can be found elsewhere in the lung. They range in size from 2 to 10 cm. Cyst walls are thin and may contain air, pus, mucus, or blood. Cysts develop from abnormal lung budding of the primitive foregut and can occur in conjunction with other congenital pulmonary malformations such as pulmonary sequestration or lobar emphysema.

Clinical Findings
Bronchogenic cysts can present acutely with respiratory distress in early childhood due to airway compression or with symptoms of infection. Other patients present with chronic symptoms such as chest pain, chronic wheezing, cough, intermittent tachypnea, recurrent pneumonia, or recurrent stridor, depending on the location and size of the cysts and the degree of airway compression. Still other patients remain asymptomatic until adulthood. However, all asymptomatic cysts will eventually become symptomatic; chest pain is the most common presenting complaint. The physical examination is often normal.

A. Laboratory Findings and Imaging Studies
The choice of diagnostic studies for bronchogenic cysts is controversial. Chest radiographs can show air trapping and hyperinflation of the affected lobes or may show a spherical lesion with or without an air-fluid level. However, smaller lesions may not be seen on chest radiographs. CT scan is the preferred imaging study and can differentiate solid versus cystic mediastinal masses and define the cyst’s relationship to the airways and the rest of the lung. A barium swallow can help determine whether the lesion communicates with the gastrointestinal tract. MRI and ultrasound are other imaging modalities used.

Treatment
Treatment is surgical resection. Resection should be performed as soon as the cyst is detected to avoid future
complications including infection. Postoperatively, vigorous pulmonary physiotherapy is required to prevent complications (atelectasis or infection of the lung distal to the site of resection of the cyst).

ACQUIRED CAUSES OF INTRATHORACIC AIRWAY OBSTRUCTION

Acquired disorders of intrathoracic airway obstruction can present acutely or with recurrent symptoms of lower airway obstruction. Children with disorders of the intrathoracic airway often present with expiratory sounds such as wheeze, recurrent cough, and/or recurrent pneumonia due to retained secretions. The differential for intrathoracic airway obstruction includes foreign body aspiration, infection, extrinsic compression not present at birth (eg, lymphadenopathy), and chronic lung diseases causing airway swelling such as disorders of mucociliary clearance, recurrent aspiration, and asthma.

FOREIGN BODY ASPIRATION IN THE INTRATHORACIC AIRWAY

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► Sudden onset of coughing, wheezing, or respiratory distress.
► Asymmetrical physical findings of decreased breath sounds or localized wheezing.
► Asymmetrical radiographic findings, especially with forced expiratory view.

Clinical Findings

A. Symptoms and Signs

Respiratory symptoms and signs vary depending on the site of obstruction and the duration following the acute episode. (See section Foreign Body Aspiration in the Extrathoracic Airway.) The acute cough or wheezing caused by a foreign body in the lower respiratory tract may diminish over time only to recur later as chronic cough or persistent wheezing, monophonic wheezing, asymmetrical breath sounds on chest examination, or recurrent pneumonia in one location.

Foreign body aspiration should be suspected in children with chronic cough, persistent wheezing, or recurrent pneumonia. Hearing asymmetrical breath sounds or localized wheezing also suggests a foreign body.

B. Laboratory Findings and Imaging Studies

Inspiratory and forced expiratory (obtained by manually compressing the abdomen during expiration) chest radiographs should be obtained if foreign body aspiration is suspected. Chest radiographs may be normal up to 17% of the time. A positive forced expiratory study shows unilateral hyperinflation and there may be a mediastinal shift away from the affected side. If obstruction of a distal airway is complete, atelectasis and related volume loss will be the major radiologic findings. Virtual bronchoscopy and computerized tomography are alternative approaches for detecting a foreign body.

Treatment

When a foreign body is highly suspected, a normal chest radiograph is not sufficient to rule out the possibility of an airway foreign body. If clinical suspicion persists based on two of three findings—history of possible aspiration, focal abnormal lung examination, or an abnormal chest radiograph—then a bronchoscopy is indicated. Rigid bronchoscopy under general anesthesia is recommended. Flexible bronchoscopy may be helpful for follow-up evaluations (after the foreign object has been removed).

Children with suspected acute foreign body aspiration should be admitted to the hospital for evaluation and treatment. Chest postural drainage is no longer recommended because the foreign body may become dislodged and obstruct a major central airway. Bronchoscopy should not be delayed in children with respiratory distress but should be performed as soon as the diagnosis is made—even in children with more chronic symptoms. Following the removal of the foreign body, β-adrenergic nebulization treatments followed by chest physiotherapy are recommended to help clear related mucus or treat bronchospasm. Failure to identify a foreign body in the lower respiratory tract can result in bronchiectasis or lung abscess. This risk justifies an aggressive approach to suspected foreign bodies in suspicious cases.

DISORDERS OF MUCOCILIARY CLEARANCE

Mucociliary clearance is the primary defense mechanism for the lung. Inhaled particles including microbial pathogens are also entrapped in mucus on the airway surface, then
Cystic fibrosis (CF), an autosomal recessive disease, results in a syndrome of chronic sinopulmonary infections, malabsorption, and nutritional abnormalities. It is one of the most common lethal genetic diseases in the United States, with an incidence of approximately 1:3000 among Caucasians and 1:9200 in the US Hispanic population. Although abnormalities occur in the hepatic, gastrointestinal, and male reproductive systems, lung disease is the major cause of morbidity and mortality. Most individuals with CF develop obstructive lung disease associated with chronic infection that leads to progressive loss of pulmonary function.

The cause of CF is a defect in a single gene on chromosome 7 that encodes an epithelial chloride channel called the CF transmembrane conductance regulator (CFTR) protein. The most common mutation is F508del, although approximately 1800 other disease-causing mutations have been identified. Gene mutations lead to absence or defects in CFTR, altering salt and water movement across cell membranes, resulting in abnormally thick secretions in various organs and critically altering host defense in the lung.

### Clinical Findings
#### A. Symptoms and Signs

All states in the United States and many other countries now perform newborn screening for CF by measuring immunoreactive trypsin (IRT), a pancreatic enzyme, in blood with or without concurrent DNA testing. Most infants with CF have elevated IRT in the newborn period, although false negative results are possible. In newborns with positive newborn screen, the diagnosis of CF must be confirmed by sweat testing, mutation analysis, or both (http://www.cff.org/AboutCF/Testing/NewbornScreening/).

Approximately 15% of newborns with CF present at birth with meconium ileus, a severe intestinal obstruction resulting from inspissation of tenacious meconium in the terminal ileum. Meconium ileus is virtually diagnostic of CF, so the infant should be treated presumptively as having CF until a sweat test or genotyping can be obtained.

During infancy and beyond, a common presentation of CF is failure to thrive due to malabsorption from exocrine pancreatic insufficiency, failure of the pancreas to produce sufficient enzymes to digest fats and protein. Children with pancreatic insufficiency fail to gain weight despite good appetite and typically have frequent, bulky, foul-smelling, oily stools. Pancreatic insufficiency occurs in more than 85% of persons with CF. (Chapter 22 describes gastrointestinal and hepatobiliary manifestations of CF; see also Table 22–12.) Infants with undiagnosed CF may also present with hypoproteinemia, anemia, and deficiency of the fat-soluble vitamins A, D, E, and K, because of ongoing steatorrhea.

CF should also be considered in children who present with severe dehydration and hypocholesterolemia, and in children with unexplained bronchiectasis, rectal prolapse, nasal polyps, chronic sinusitis, and unexplained pancreatitis or cirrhosis. Respiratory symptoms can include productive cough, wheezing, recurrent pneumonia, progressive obstructive airways disease, exercise intolerance, dyspnea, and hemoptysis. Chronic airway infection with bacteria, including *S. aureus* and *H. influenzae*, often begins in the first few months of life, even in asymptomatic infants. Eventually, *Pseudomonas aeruginosa* and other gram-negative opportunistic bacteria become the predominant pathogens. Chronic infection leads to airflow obstruction and progressive airway and lung destruction resulting in bronchiectasis.

Episodic increases in respiratory symptoms are generically termed pulmonary exacerbations. Clinically, an exacerbation manifests by increased cough and sputum production, decreased exercise tolerance, malaise, and weight loss, and decrease in measures of lung function. Treatment for pulmonary exacerbations generally consists of antibiotics and augmented airway clearance.

#### B. Laboratory Findings and Imaging Studies

The diagnosis of CF is made by a sweat chloride concentration greater than 60 mmol/L in the presence of one or more typical clinical features (chronic sinopulmonary disease, pancreatic insufficiency, salt loss syndromes) or family history (sibling or first cousin who has CF). Sweat tests should
be performed at a CF Foundation–accredited laboratory. A diagnosis can also be confirmed by genotyping that reveals two disease-causing mutations (www.cftr2.org).

Intermediate sweat chloride values of 30–60 may be associated with mild CFTR mutations that result in residual functioning CFTR protein. Patients with residual CFTR function typically have adequate pancreatic exocrine function, but may develop severe lung disease. CFTR-related metabolic syndrome, diagnosed based on elevated IRT on newborn screen but sweat test less than 60 mmol/L and up to two CFTR mutations, at least one of which is not considered disease-causing, appears to have an even milder disease phenotype. The natural history of this condition is still being defined.

Treatment

It is strongly recommended that individuals with CF be followed at a CF Foundation–accredited CF care center (http://www.cff.org). Care is provided with a multidisciplinary team approach that includes pulmonologists and advanced practice providers trained in CF care, nurses, respiratory therapists, dietitians, social workers, and psychologists. Recently a large study highlighted the importance of screening for depression and anxiety in patients with CF, as these are prevalent and negatively impact quality of life and adherence to treatment regimens.

The cornerstone of gastrointestinal treatment is pancreatic enzyme supplementation combined with a high-calorie, high-protein, and high-fat diet. Persons with CF are required to take pancreatic enzyme immediately prior to each meal and with snacks and should also take daily multivitamins that contain vitamins A, D, E, and K. Caloric supplements are often added to the diet to optimize growth. Daily salt supplementation also is required to prevent hyponatremia, especially during hot weather.

Airway clearance therapy and aggressive antibiotic use form the mainstays of treatment for CF lung disease. Antibiotic therapy appears to be one of the primary reasons for the increased life expectancy of persons with CF. Respiratory treatments typically include recombinant human dornase alpha, inhaled hypertonic saline, and for those with chronic Pseudomonas infection, anti-pseudomonal antibiotics (tobramycin or aztreonam), and oral azithromycin. These therapies have been shown to maintain lung function and reduce the need for hospitalizations and intravenous antibiotics. Early detection of Pseudomonas aeruginosa and treatment with inhaled tobramycin can often eradicate the bacteria and delay chronic infection. Bronchodilators and anti-inflammatory therapies are also frequently used.

Recent clinical trials using protein-rescue therapies to improve CFTR function (termed CFTR modulators) have shown encouraging results. The first treatment that directly works to correct the function of the defective CF protein was approved in 2012. This drug, ivacaftor, is currently approved for use in patients aged 2 and older with at least one gating mutation (eg, G551D) or the R117H CFTR mutation, which includes about 6% of CF patients. A second CFTR modulator, ivacaftor combined with lumacaftor, also was recently approved for affected individuals aged 6 and older who are F508del homozygous. Ongoing trials of these and other CFTR modulators may extend treatments to patients who are F508del heterozygous or have other mutations.

Prognosis

A few decades ago, CF was fatal in early childhood. Now the median life expectancy is around 40 years of age. The rate of lung disease progression usually determines survival. Lung transplantation may be performed in those with end-stage lung disease. In addition, new treatments, including gene therapy and gene editing trials and improved CFTR modulators, are in development to improve life expectancy and quality of life.

Boyle MP et al: A CFTR corrector (lumacaftor) and a CFTR potentiator (ivacaftor) for treatment of patients with cystic fibrosis who have a phe508del CFTR mutation: a phase 2 randomized controlled trial. Lancet Respir Med 2014 Jul;2(7):527–538 [PMID: 24973281].

Primary ciliary dyskinesia (PCD), also known as immotile cilia syndrome, is a rare, inherited, usually autosomal recessive disorder with impaired ciliary function leading to progressive sinopulmonary disease. It is believed to occur in approximately 1 in 15,000 births. Almost half of patients with PCD have situs abnormalities, and men are usually
infertile. The triad of situs inversus totalis, bronchiectasis, and chronic sinusitis is known as Kartagener syndrome.

» Clinical Findings

A. Symptoms and Signs

Situs inversus totalis occurs in approximately 50% of patients with PCD. Conversely, 20% of children with situs inversus totalis have PCD. Upper and lower respiratory tract manifestations are cardinal features of PCD. The majority of children with PCD present in the immediate newborn period with respiratory distress (commonly diagnosed as neonatal pneumonia or transient tachypnea of the newborn) and often require supplemental oxygen. Upper respiratory tract problems include chronic year-round nasal drainage that may begin in the first weeks of life, chronic sinusitis, nasal polyps, and chronic serous otitis media. Conductive hearing loss with chronic middle ear effusion is common. If myringotomy tubes are placed, chronic otorrhea often ensues. Lower respiratory tract features include chronic year-round productive cough, chronic and recurrent bronchitis, and recurrent pneumonia. They are at risk to develop obstructive lung disease and bronchiectasis.

Nonrespiratory ciliopathies that have been associated with PCD include heterotaxy, asplenia, polysplenia, congenital heart disease, autosomal dominant polycystic kidney disease, retinitis pigmentosa, biliary atresia, and hydrocephalus.

B. Laboratory Findings and Imaging Studies

The diagnosis of PCD currently requires a compatible clinical phenotype and identification of ultrastructural and/or functional defects of the cilia. Examination of ciliary ultra-structure by transmission electron microscopy (EM) remains the cornerstone test for PCD. Cilia samples may be obtained from either the upper airways (nasal passage) or lower airways (trachea). Semen collection from older male patients can also be obtained to analyze sperm tails, which have the same ultrastructure as cilia. Significant expertise is required to produce high-quality transmission electron micrographs of cilia, and to distinguish primary (genetic) defects from secondary (acquired) defects in ciliary ultrastructure. Multiple different defects in EM can occur including abnormalities in the outer dynein arm, inner dynein arms, radial spokes, and the central apparatus. Some patients with PCD can also have normal EM ultrastructure. The use of EM can help to identify approximately 70% of PCD cases. Ciliary beat frequency or airway epithelium cultures are also used for diagnosis in some settings. In patients with a compatible clinical history but without visible ultrastructural defects, very low levels of nasal nitric oxide are a useful screening and adjunctive diagnostic test in children ages 5 and older. Genetic testing is emerging for PCD and demonstrates extensive genetic heterogeneity. Some genes and gene mutations involved in PCD have been defined. Approximately 70% of PCD cases have identifiable gene mutations in one of 33 known PCD genes, although new genes are expected to be identified as PCD causing.

» Treatment

At present, no specific therapies are available to correct the ciliary dysfunction in PCD. Treatment is not evidence-based and recommendations are largely extrapolated from CF and other suppurative lung diseases. Respiratory management includes routine pulmonary monitoring (lung function testing, respiratory cultures, chest imaging), airway clearance by combinations of physiotherapy and physical exercise, and aggressive treatment of upper and lower airways infections.

» Prognosis

The progression of lung disease in PCD is quite variable. Importantly, persons with PCD are at risk for chronic obstructive lung disease with bronchiectasis. With monitoring and aggressive treatment during times of illness, most individuals with PCD should experience a normal or near-normal life span.

Bronchiectasis

» Chronic cough with sputum production.

» Rhonchi or wheezes (or both) on chest auscultation.

» Diagnosis is confirmed by high-resolution CT scan.

» Pathogenesis

Bronchiectasis is the permanent dilation of bronchi resulting from airway obstruction by retained mucus secretions or inflammation in response to chronic or repeated infection. It occurs either as a consequence of a preceding illness (severe pneumonia or foreign body aspiration) or as a manifestation of an underlying systemic disorder leading to chronic airway
inflammation and injury (CF, PCD, chronic aspiration, or immunodeficiency).

Clinical Findings

A. Symptoms and Signs

Persons with bronchiectasis will typically have chronic cough, purulent sputum, fever, and weight loss. Recurrent respiratory infections and dyspnea on exertion are also common. Hemoptysis occurs less frequently in children than in adults with bronchiectasis. On physical examination, finger clubbing may be seen. Rales, rhonchi, and decreased air entry are often noted over the bronchiectatic areas.

B. Laboratory Findings and Imaging Studies

The most common bacteria detected in cultures from the lower respiratory tract include S pneumoniae, S aureus, non-typeable H influenzae, and P aeruginosa. Nontuberculous mycobacterial species may also be detected in patients with bronchiectasis.

Chest radiographs may be mildly abnormal with slightly increased bronchovascular markings or areas of atelectasis, or they may demonstrate cystic changes in one or more areas of the lung. The extent of bronchiectasis is best defined by high-resolution CT, which often reveals far wider involvement of lung than expected from the chest radiograph. Airflow obstruction and air trapping often is seen on pulmonary function testing. Evaluation of lung function after use of a bronchodilator is helpful in assessing the benefit from bronchodilators. Serial assessments of lung function help define the progression or resolution of the disease.

Differential Diagnosis

Bronchiectasis has numerous causes. It can occur following severe respiratory tract infections by bacteria (S aureus, Bordetella pertussis), viruses (adenovirus), or other organisms (M tuberculosis). Bronchiectasis can also be due to persistent inflammation and is commonly seen in persons with recurrent aspiration pneumonia, CF, PCD, immunodeficiency, surfactant deficiencies, and collagen-vascular conditions. Other diagnostic considerations include foreign body aspiration and allergic bronchopulmonary aspergillosis.

Treatment

Aggressive antibiotic therapy during pulmonary exacerbations and routine airway clearance are mainstays of treatment. Chronic antibiotic use, anti-inflammatory therapy, hyperosmolar agents (hypertonic saline), and bronchodilators have not proven effective in non-CF bronchiectasis, although individual patients may benefit. However, a large study in adults with idiopathic bronchiectasis concluded that those who received dornase alpha twice a day had more frequent exacerbations, hospitalizations, and lower lung function compared to placebo; thus, dornase alpha is not indicated in adult idiopathic bronchiectasis. Chronic azithromycin was recently shown to reduce exacerbations in adults with non-CF bronchiectasis. Whether these results translate to children with idiopathic bronchiectasis is not known.

Surgical removal of an area of lung affected with severe bronchiectasis is considered when the response to medical therapy is poor. Other indications for operation include severe localized disease, repeated hemoptysis, and recurrent pneumonia in one area. If bronchiectasis is widespread, surgical resection offers little advantage.

Prognosis

The prognosis depends on the underlying cause and severity of bronchiectasis, the extent of lung involvement, and the response to medical management. Good pulmonary hygiene and avoidance of infectious complications in the involved areas of lung may reverse cylindrical bronchiectasis.

PULMONARY AGENESIS & HYPOPLASIA

Pulmonary aplasia is not compatible with life.
Pulmonary hypoplasia is due to incomplete development.
Pulmonary hypoplasia often leads to prolonged oxygen requirement and increased oxygen need with illness and activity. Other symptoms vary by degree of hypoplasia.

In unilateral pulmonary agenesis (complete absence of one lung), the trachea continues into a main bronchus and often has complete tracheal rings. With compensatory postnatal growth, the remaining lung often herniates into the contralateral chest. Chest radiographs show a mediastinal shift toward the affected side. Absent or incomplete lung development may be associated with vertebral and other congenital
abnormalities, such as absence of one or both kidneys or fusion of ribs, and the outcome is primarily related to the severity of associated lesions. About 37% of patients survive; the mortality rate is higher with agenesis of the right lung than of the left lung. This difference is probably not related to the higher incidence of associated anomalies but rather to a greater shift in the mediastinum that leads to tracheal compression and distortion of vascular structures.

Pulmonary hypoplasia is incomplete development of one or both lungs, characterized by a reduction in alveolar number and a reduction in airway branches. Pulmonary hypoplasia is present in up to 10%–15% of perinatal autopsies. The hypoplasia can be a result of an intrathoracic mass, resulting in lack of space for the lungs to grow; decreased size of the thorax; decreased fetal breathing movements; decreased blood flow to the lungs; or possibly a primary mesodermal defect affecting multiple organ systems. Congenital diaphragmatic hernia is the most common cause. Other causes include extralobar sequestration, diaphragmatic evagination or hypoplasia, thoracic neuroblastoma, fetal hydrops, and fetal hydrothorax. Chest cage abnormalities, diaphragmatic elevation, oligohydramnios, chromosomal abnormalities, severe musculoskeletal disorders, and cardiac lesions may also result in hypoplastic lungs. Postnatal factors may play important roles. For example, infants with advanced BPD can have pulmonary hypoplasia.

Clinical Findings
A. Symptoms and Signs
The clinical presentation is highly variable and related to the severity of hypoplasia as well as associated abnormalities. Lung hypoplasia is often associated with pneumothorax in newborns. Some newborns present with perinatal stress, severe acute respiratory distress, and persistent pulmonary hypertension secondary to primary pulmonary hypoplasia (without associated anomalies). Children with lesser degrees of hypoplasia may present with chronic cough, tachypnea, wheezing, and recurrent pneumonia.

B. Laboratory Findings and Imaging Studies
Chest radiographic findings include variable degrees of volume loss in a small hemithorax with mediastinal shift. Pulmonary agenesis should be suspected if tracheal deviation is evident on the chest radiograph. The chest CT scan is the optimal diagnostic procedure if the chest radiograph is not definitive, though ultrasound or fetal MRI are also used for prenatal diagnosis. Ventilation-perfusion scans, angiography, and bronchoscopy are often helpful in the evaluation, demonstrating decreased pulmonary vascularity or premature blunting of airways associated with the maldeveloped lung tissue. The degree of respiratory impairment is defined by analysis of arterial blood gases.

Treatment & Prognosis
Treatment is supportive. The outcome is determined by the severity of underlying medical problems, the extent of the hypoplasia, and the degree of pulmonary hypertension.

Pulmonary Sequestration
ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Congenital lung malformation with a blood supply from systemic arteries usually found in a lower lobe.
- Often presents with recurrent pneumonia or chronic cough.
- Diagnosed postnatally by chest CT.

Pulmonary sequestration is the second most common congenital lung abnormality, and is characterized by nonfunctional pulmonary tissue that does not communicate with the tracheobronchial tree and receives its blood supply from one or more anomalous systemic arteries. This abnormality originates during the embryonic period of lung development. It is classified as either extralobar or intralobar.

Extralobar sequestration is a mass of pulmonary parenchyma anatomically separate from the normal lung, with a distinct pleural investment. Its blood supply derives from the systemic circulation (more typical), from pulmonary vessels, or from both. Rarely, it communicates with the esophagus or stomach. Pathologically, extralobar sequestration appears as a solitary thoracic lesion near the diaphragm. Abdominal sites are rare. Size varies from 0.5 to 12 cm. The left side is involved in more than 65% of cases. In contrast to intralobar sequestrations, venous drainage is usually through the systemic or portal venous system.

Intralobar sequestration is an isolated segment of lung within the normal pleural investment that often receives blood from one or more arteries arising from the aorta or its branches. Intralobar sequestration is usually found within the lower lobes (98%), 55% are found on the left side, and it is rarely associated with other congenital
anomalies (< 2% vs 50% with extralobar sequestration). It rarely presents in the newborn period (unlike extralobar sequestration). Some researchers have hypothesized that intralobar sequestration is an acquired lesion secondary to chronic infection.

Clinical Findings, Imaging, and Treatment

Clinical presentation includes chronic cough, wheezing, or recurrent pneumonias. Rarely, patients with intralobar sequestration present with hemoptysis. Diagnosis is often suggested by CT imaging postnatally, though it can be diagnosed via prenatal ultrasound. Definitive diagnosis can be made by angiography, which shows large systemic arteries perfusing the lesion. Spiral CT scans with contrast or magnetic resonance angiography have proved useful in identifying anomalous systemic arterial supply to the lung. Treatment is surgical resection.

CONGENITAL LOBAR OVERINFLATION

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Presents in the first year of life and may be diagnosed prenatally.
- Chest imaging shows overinflation of the affected lobe (usually right upper or middle).

Patients with congenital lobar overinflation (CLO)—also known as congenital lobar emphysema, congenital localized emphysema, unilobar obstructive emphysema, congenital hypertrophic lobar emphysema, or congenital lobar overinflation—present most commonly with neonatal respiratory distress or progressive respiratory impairment during the first year of life. Rarely the mild or intermittent nature of the symptoms in older children or young adults results in delayed diagnosis. Most patients are white males. Although the cause of congenital lobar emphysema is not well understood, some lesions show bronchial cartilaginous dysplasia due to abnormal orientation or distribution of the bronchial cartilage or other cause of bronchial obstruction, leading to a partial ball-valve effect and resultant air trapping. This leads to expiratory collapse, producing obstruction and air trapping.

Clinical Findings

A. Symptoms and Signs

Clinical features include respiratory distress, tachypnea, cyanosis, wheezing, retractions, and cough. Breath sounds are reduced on the affected side, perhaps with hyperresonance to percussion, mediastinal displacement, and bulging of the chest wall.

B. Imaging Studies

Radiologic findings include overdistention of the affected lobe (usually an upper or middle lobe; > 99%), with wide separation of bronchovascular markings, collapse of adjacent lung, shift of the mediastinum away from the affected side, and a depressed diaphragm on the affected side. The radiographic diagnosis may be confusing in the newborn because of retention of alveolar fluid in the affected lobe causing the appearance of a homogeneous density. Other diagnostic studies include chest radiograph with fluoroscopy, ventilation-perfusion study, and chest CT scan followed by bronchoscopy, angiography, and exploratory thoracotomy.

Differential Diagnosis

The differential diagnosis of CLO includes pneumothorax, pneumatocele, atelectasis with compensatory hyperinflation, diaphragmatic hernia, and congenital cystic adenomatoid malformation. The most common site of involvement is the left upper lobe (42%) or right middle lobe (35%). Evaluation must differentiate regional obstructive emphysema from lobar hyperinflation secondary to an uncomplicated ball-valve mechanism due to extrinsic compression from a mass (ie, bronchogenic cyst, tumor, lymphadenopathy, foreign body, pseudotumor or plasma cell granuloma, or vascular compression) or intrinsic obstruction from a mucus plug due to infection and inflammation from various causes.

Treatment

When respiratory distress is marked, a segmental or complete lobectomy is usually required. Less symptomatic and older children may do equally well with or without lobectomy.

CONGENITAL PULMONARY AIRWAY MALFORMATION (CYSTIC ADENOMATOID MALFORMATION)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

» May be diagnosed prenatally by ultrasound.
» Newborns generally present with respiratory distress and evidence of a space occupying density on chest x-ray.

Congenital pulmonary airway malformations (CPAMs; previously known as congenital cystic adenomatoid malformations) are unilateral hamartomatous lesions which generally present with marked respiratory distress within the first days of life. This disorder accounts for 95% of cases of congenital cystic lung disease.

Right and left lungs are involved with equal frequency. These lesions originate in the first 5–22 weeks of gestation during the embryonic period of lung development. They appear as glandlike, space-occupying masses or have an increase in terminal respiratory structures, forming inter-communicating cysts of various sizes, lined by cuboidal or ciliated pseudostratified columnar epithelium. The lesions may have polypoid formations of mucosa, with focally increased elastic tissue in the cyst wall beneath the bronchial type of epithelium. Air passages appear malformed and tend to lack cartilage.

There are five types of such malformations (Table 19–5).

Clinical Findings

A. Symptoms and Signs

Clinically, respiratory distress may be noted soon after birth. Expansion of the cysts occurs with the onset of breathing and produces compression of normal lung areas with mediastinal herniation. Breath sounds are decreased. With type 3 lesions, dullness to percussion may be present. Older patients can present with a spontaneous pneumothorax or with pneumonia-like symptoms. Recently increasing numbers of patients are diagnosed with these lesions on prenatal ultrasound.

B. Laboratory Findings and Imaging Studies

Chest radiographic findings differ by the type of lesion. Placement of a radiopaque feeding tube into the stomach helps in the differentiation from diaphragmatic hernia. Differentiation from sequestration is not difficult because congenital CPAMs have no systemic blood supply.

Treatment

In cases of prenatal diagnosis, treatment is variable and does not need antenatal intervention. Attention must be paid to the development of hydrops as a complication of these lesions. Postnatal treatment of types 1 and 3 lesions involves surgical removal of the affected lobe. Resection is often indicated because of the risk of infection and air trapping, since the malformation communicates with the tracheobronchial tree but mucus clearance is compromised. Because type 2 lesions are often associated with other severe anomalies, management may be more complex. Segmental resection is not feasible because smaller cysts may expand after removal of the more obviously affected area. Of note, some CPAMs have been shown to spontaneously resolve. However, CPAMs have been reported to have malignant potential; therefore, expectant management with observation alone should proceed with caution. Recent development of intrauterine surgery for congenital malformations has led to promising results.

ACQUIRED ABNORMALITIES OF THE LUNG PARENCHYMA

BRONCHOPULMONARY DYSPLASIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Acute respiratory distress in the first week of life.
- Required oxygen therapy or mechanical ventilation, with persistent oxygen requirement at 36 weeks’ gestational age or 28 days of life.
- Persistent respiratory abnormalities, including physical signs and radiographic findings.

BPD remains one of the most significant sequelae of acute respiratory distress in the neonatal intensive care unit, with an incidence as high as 68% for infants born at 22–28 weeks’ gestation. This disease was first characterized in 1967 when Northway reported the clinical, radiologic, and pathologic findings in a group of preterm newborns that required prolonged mechanical ventilation and oxygen therapy.

The pathologic findings and clinical course of BPD have changed over time due to technological advances (artificial surfactant, antenatal steroids) and protective/noninvasive ventilatory strategies. Improvements in care have also increased survival of infants born at earlier gestational ages. Extremely preterm infants born at less than 28 weeks’ gestation are at risk to develop “new” BPD and arrest of lung development, which is characterized by alveolar simplification and vascular hypoplasia that can lead to sequelae, such as impaired gas exchange, exercise intolerance, and pulmonary hypertension.

The mechanisms that cause BPD are unclear. Current studies suggest that structural immaturity of the alveolar-capillary network, surfactant deficiency, atelectasis, and pulmonary edema cause impaired gas exchange and, potentially, respiratory failure. Mechanical ventilation and supplemental oxygen, though necessary to sustain life, may result in barotrauma and oxidative stress. Excessive fluid administration, patent ductus arteriosus, pulmonary interstitial emphysema, pneumothorax, infection, pulmonary hypertension, and inflammatory stimuli secondary to lung injury or infection also play important roles in the pathogenesis of the disease. Infants can develop aggressive, fibroproliferative pathologic lesions as well as physiologic abnormalities (increased airway resistance) and biochemical markers of lung injury that may predict BPD during the first weeks of life. Ongoing injuries may further contribute to ventilator and oxygen dependence. The lungs of extremely preterm newborns with BPD show simplified histology with fewer alveoli, early inflammation, and hypercellularity followed by healing with fibrosis.

Clinical Findings

The clinical definition of BPD includes the need for postnatal oxygen after 28 days. The severity of BPD is determined by a physiologic assessment of oxygen status at 36 weeks’ gestation or on day of life 28 for infants born after 32 weeks’ gestation. Full-term newborns with such disorders as meconium aspiration, congenital diaphragmatic hernia, and persistent pulmonary hypertension also can develop BPD.

The clinical course of infants with BPD ranges from an oxygen requirement that gradually resolves over a few months to more severe disease requiring tracheostomy for chronic mechanical ventilation during early childhood. In general, patients show slow, steady improvements in oxygen or ventilator requirements. Clinical management also includes paying careful attention to growth and nutrition (infants with oxygen dependence have high caloric requirements), and partnering with developmental therapists to ensure the optimal neurocognitive outcomes.

Treatment

A. Medical Therapy

Early use of surfactant therapy with adequate lung recruitment increases the chance for survival without BPD, reduces the need for mechanical ventilation, and can decrease the overall mortality. Short courses of postnatal glucocorticoid therapy have been helpful in increasing the success of weaning from the ventilator. Longer courses of postnatal glucocorticoids have been linked to an increased incidence of cerebral palsy. The effect of inhaled corticosteroids and β-adrenergic agonists on the course of BPD is not clear.

Salt and water retention secondary to chronic hypoxemia, hypercapnia, or other stimuli may be present. Chronic or intermittent diuretic therapy is commonly used if pulmonary edema is present. Clinical studies show acute improvement in lung function with this therapy, but long-term outcomes are not directly related to acute improvement. Unfortunately, diuretics often have adverse effects, including volume contraction, hypokalemia, alkalosis, hyponatremia, and nephrocalcinosis. Potassium and arginine chloride supplements may be required.
B. Airway Evaluation
Children with significant stridor, sleep apnea, chronic wheezing, or excessive respiratory distress require diagnostic bronchoscopy to evaluate for structural lesions (eg, subglottic stenosis, vocal cord paralysis, tracheal or bronchial stenosis, tracheobronchomalacia, or airway granulomas). The contribution of gastroesophageal reflux and aspiration should be considered in the face of worsening chronic lung disease.

C. Management of Pulmonary Hypertension
Infants with BPD are at risk of developing pulmonary hypertension. In many of these children even mild hypoxemia can cause significant elevations of pulmonary arterial pressure. To minimize the harmful effects of hypoxemia, the arterial oxygen saturation should be kept above 93% in children with pulmonary hypertension, with care to avoid hyperoxia during retinal vascular development. Electrocardiographic and echocardiographic studies should be performed to monitor for the development of right ventricular hypertrophy. Management of neonatal pulmonary hypertension should involve expert consultation with a pulmonary hypertension specialist. Cardiac catheterization may be necessary to diagnose unsuspected cardiac or pulmonary lesions and to measure the response of the pulmonary vasculature to vasodilators such as inhaled nitric oxide before chronic therapy, such as with oral sildenafil, is initiated. Barium esophagram, esophageal pH/impedence studies, a sleep study or overnight pulse oximetry, and bronchoscopy may aid in diagnosing gastroesophageal reflex, aspiration, obstructive sleep apnea, and airway abnormalities that contribute to the underlying pathophysiology. Long-term care should include monitoring for systemic hypertension and the development of left ventricular hypertrophy.

D. Nutrition and Immunizations
Nutritional problems in infants with BPD may be due to increased oxygen consumption, feeding difficulties, gastroesophageal reflux, and chronic hypoxemia. Hypercaloric formulas and gastrostomy tubes are often required to ensure adequate intake while avoiding overhydration. Routine vaccinations including the influenza vaccine are recommended. Immune prophylaxis of RSV reduces the severity morbidity of bronchiolitis in infants with BPD. In children older than 2 years with severe BPD, pneumococcal polysaccharide 23-valent vaccine should be considered in addition to standard pneumococcal vaccination.

E. Ventilation
For children with BPD who remain ventilator-dependent, attempts should be made to maintain PaCO$_2$ below 60 mm Hg—even when pH is normal—because of the potential adverse effects of hypercapnia on salt and water retention, cardiac function, and perhaps pulmonary vascular tone. Changes in ventilator settings in children with severe lung disease should be slow, because the effects of many of the changes may not be apparent for days.

Differential Diagnosis
The differential diagnosis of BPD includes meconium aspiration syndrome, congenital infection (eg, with cytomegalovirus or Ureaplasma), cystic adenomatoid malformation, recurrent aspiration, pulmonary lymphangiectasia, total anomalous pulmonary venous return, overhydration, childhood ILD, and idiopathic pulmonary fibrosis.

Prognosis
Surfactant replacement therapy has had a markedly beneficial effect on reducing morbidity and mortality from BPD. The incidence of BPD and chronic lung disease due to prematurity is increasing due to increased survival or early and extremely preterm infants. The long-term outlook for most survivors is favorable, although follow-up studies suggest that lung function may be altered for life. As smaller, more immature infants survive, abnormal neurodevelopmental outcomes become more likely. The incidence of cerebral palsy, hearing/visual impairment, and developmental delays is increased. Feeding abnormalities, behavior difficulties, and increased irritability have also been reported. A focus on good nutrition, prophylaxis against respiratory infection, developmental therapies (physical, occupational, and speech), attention to neurocognitive function, and family support provide the best outcomes.

COMMUNITY-ACQUIRED BACTERIAL PNEUMONIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Fever, cough, dyspnea.
- Abnormal chest examination (crackles or decreased breath sounds).
- Abnormal chest radiograph (infiltrates, hilar adenopathy, pleural effusion).
Lower respiratory tract infections are a major cause of childhood mortality in disadvantaged areas of the world. The infectious etiologies vary widely by geographic region and by the age of the child. In developed countries, the majority of pneumonias are caused by viral agents and bacterial pneumonia is a less common cause. Discrimination between viral and bacterial pneumonia is challenging as neither the white blood cell count nor differential nor the chest radiograph are strong predictors. In areas where the technology is readily available, chest radiography is recommended to establish with certainty the presence of pneumonia. The most common cause of bacterial pneumonia in children of all ages is *S. pneumoniae*. Bacterial pneumonia usually follows a viral lower respiratory tract infection. Children at high risk for bacterial pneumonia are those with compromised pulmonary defense systems. For example, children with abnormal mucociliary clearance, immunocompromised children, children who aspirate their own secretions or while eating, and malnourished children are at increased risk for bacterial pneumonia.

### Clinical Findings

#### A. Symptoms and Signs

The pathogen, severity of the infection, and age of the patient may cause substantial variations in the presentation of community-acquired pneumonia (CAP). Fever (over 39°C), tachypnea, and cough are hallmarks of CAP. Chest auscultation may reveal crackles or decreased breath sounds in the setting of consolidation or an associated pleural effusion. Some patients may have additional extrapulmonary findings, such as meningismus or abdominal pain, due to pneumonia itself. Others may have evidence of infection at other sites due to the same organism causing their pneumonia: meningitis, otitis media, sinusitis, pericarditis, epiglottitis, or abscesses.

#### B. Laboratory Findings and Imaging Studies

An elevated peripheral white blood cell count with a left shift may be a marker of bacterial pneumonia. A low white blood count (< 5000/μL) can be an ominous finding in this disease. Blood cultures should be obtained in children admitted to the hospital with pneumonia, although approximately 10% or less will be positive. Sputum cultures may be helpful in older children capable of providing a satisfactory sample. Invasive diagnostic procedures (bronchial brushing or washing, lung puncture, or open or thoracoscopic lung biopsy) should be undertaken in critically ill patients when other means do not adequately identify the cause (see section Diagnosis of Respiratory Tract Infections).

The spectrum of potential pathogens to be considered includes aerobic, anaerobic, and acid-fast bacteria as well as other atypical bacteria and respiratory viruses. *S. pneumoniae* is the most prevalent bacterial pathogen. Viral antigen immunofluorescent staining (DFA) and polymerase chain reactivity (PCR) technology has improved the ability to detect a wide variety of viral infections.

Air-space disease or consolidation in a lobar distribution on chest x-ray suggests bacterial pneumonia; interstitial or peribronchial infiltrates suggest a viral infection. Severity of the infection may not correlate with radiographic findings and clinical improvement precedes radiographic resolution. If a pleural effusion is suspected, radiographs should be taken in the lateral decubitus position. A diagnostic (and possibly therapeutic) thoracocentesis should also be performed in a child with a pleural effusion.

#### Differential Diagnosis

Noninfectious pulmonary disease (including gastric aspiration, foreign body aspiration, atelectasis, congenital malformations, congestive heart failure, malignancy, tumors such as plasma cell granuloma, chronic ILD, and pulmonary hemosiderosis) should be considered in the differential diagnosis of localized or diffuse infiltrates. When effusions are present, additional noninfectious disorders such as collagen diseases, neoplasm, and pulmonary infarction should also be considered.

#### Laboratory Findings and Imaging Studies

Empyema can occur frequently with staphylococcal, pneumococcal, and group A β-hemolytic streptococcal pneumonia. Distal sites of infection—meningitis, otitis media, sinusitis (especially of the ethmoids), and sepsis—may be present, particularly with disease due to *S. pneumoniae* or *H. influenzae*. Certain immunocompromised patients, such as those who have undergone splenectomy or who have hemoglobin SS or SC disease or thalassemia, are especially prone to overwhelming sepsis with these organisms.

#### Treatment

If a bacterial pneumonia is suspected, empiric antibiotic therapy should be considered. Children younger than 4 weeks should be treated with ampicillin and an aminoglycoside. Infants 4–12 weeks of age should be treated with IV ampicillin for 7–10 days. Children 3 months to 5 years of age should be treated with oral amoxicillin (50–90 mg/kg/dose) for 7–10 days. Children older than 5 years should also be treated with amoxicillin (50–90 mg/kg/dose) for 7–10 days. Macrolide antibiotics should be used if an atypical infection is suspected. When possible, therapy can be guided by the antibiotic sensitivity pattern of the organisms isolated. (For further discussion, see Chapter 39.) All children younger than 3 months should be admitted for treatment. Whether older children should be hospitalized depends on age, the severity of illness, the suspected organism, and...
the anticipated reliability of adherence to the treatment regimen at home. Moderate to severe respiratory distress, apnea, hypoxemia, poor feeding, clinical deterioration on treatment, or associated complications (large effusions, empyema, or abscess) indicate the need for immediate hospitalization. Careful outpatient follow-up within 12 hours to 5 days is indicated in those not admitted.

Additional therapeutic considerations include oxygen, humidification of inspired gases, hydration and electrolyte supplementation, and nutrition. Removal of pleural fluid for diagnostic purposes is indicated to guide antimicrobial therapy, and may be required for therapeutic purposes.

**Prognosis**

In developed countries, for the immunocompetent host in whom bacterial pneumonia is adequately recognized and treated, the survival rate is high. For example, the mortality rate from uncomplicated pneumococcal pneumonia is less than 1%. If the patient survives the initial illness, persistently abnormal pulmonary function following empyema is surprisingly uncommon, even when treatment has been delayed or inappropriate.

The most common organism associated with empyema is *S. pneumoniae*. Other common organisms include *H. influenzae* and *S. aureus*. Less common causes are group A streptococci, gram-negative organisms, anaerobic organisms, and *M. pneumoniae*. Effusions associated with tuberculosis are almost always sterile and constitute an inflammatory reaction.

**Clinical Findings**

**A. Symptoms and Signs**

Patients usually present with typical signs of pneumonia, including fever, tachypnea, and cough. They may have chest pain, decreased breath sounds, and dullness to percussion on the affected side and may prefer to lie on the affected side. With large effusions, there may be tracheal deviation to the contralateral side. Empyema is more likely to occur in children less than 5 years.

**B. Diagnostic Studies**

The white blood cell count is often elevated, with left shift. Blood cultures are sometimes positive. The tuberculin skin test is positive in most cases of tuberculosis. Thoracentesis reveals findings consistent with an exudate. Cells in the pleural fluid are usually neutrophils in bacterial disease and lymphocytes in tuberculous effusions. In bacterial disease, pleural fluid pH and glucose are often low. A pH less than 7.2 suggests active bacterial infection. The pH of the specimen should be determined in a blood gas syringe sent to the laboratory on ice. Extra heparin should not be used in the syringe as it can falsely lower the pH. Although in adults the presence of low pH and glucose indicates the need for aggressive and thorough drainage procedures, the prognostic significance of these findings in children is unknown. Gram stain, cultures, and antigen detection are often positive for the offending organism.

The presence of pleural fluid is suggested by a homogeneous density that obscures the underlying lung on chest radiograph. Large effusions may cause a shift of the mediastinum to the contralateral side. Small effusions may only blunt the costophrenic angle. Lateral decubitus radiographs may help to detect freely movable fluid by demonstrating a layering-out effect, unless the fluid is loculated. Ultrasonography can be extremely valuable in localizing the fluid and detecting loculations, especially when thoracentesis is contemplated, but availability may be limited. Chest CT scan can help determine whether the fluid is intraparenchymal or extraparenchymal and can direct further care of complicated pneumonias.

**Treatment**

After initial thoracentesis and identification of the organism, appropriate intravenous antibiotics and adequate drainage of the fluid are the mainstay of therapy. Although
there is a trend toward managing smaller pneumococcal empyemas without a chest tube, larger effusions require chest tube drainage. Early interventions using thoracoscopic techniques such as VATS done by an experienced surgeon may reduce morbidity and shorten the length of hospital stay. While there is growing use of VATS as first-line therapy, it is not standard of care. Studies in adults show that aggressive management with drainage of pleural cavity fluid and release of adhesions with fibrinolitics is cost effective and decreases the length of stay. There are limited studies of fibrinolitics in children. The therapeutic choice will vary depending on the resources available and the preferences of the clinician.

» Prognosis
The prognosis is related to the severity of disease but is generally excellent, with complete or nearly complete recovery in most instances.

ATYPICAL PNEUMONIAS

VIRAL PNEUMONIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► Upper respiratory infection prodrome (fever, coryza, cough, hoarseness).
► Wheezing or rales.
► Myalgia, malaise, headache (older children).

Viral infection is a common cause of community-acquired pneumonia in children. Viral pneumonia is most common in children younger than 2 years. RSV, parainfluenza (1, 2, and 3) viruses, influenza (A and B) viruses, and human metapneumovirus are responsible for the large majority of cases. Severity of disease, severity of fever, radiographic findings, and the characteristics of cough or lung sounds do not reliably differentiate viral from bacterial pneumonias. Furthermore, viral infections may predispose to bacterial pneumonia. However, substantial pleural effusions, pneumatoceles, abscesses, lobar consolidation with lobar volume expansion, and “round” pneumonias are generally inconsistent with viral disease.

► Clinical Findings

A. Symptoms and Signs
An upper respiratory infection frequently precedes the onset of lower respiratory disease due to viruses. Although wheezing or stridor may be prominent in viral disease, other findings, such as cough, signs of respiratory distress (tachypnea, retractions, grunting, and nasal flaring), and physical findings (rales and decreased breath sounds) are similar to those in bacterial pneumonia.

B. Laboratory Findings
The peripheral white blood cell count can be normal or slightly elevated and is not useful in distinguishing viral from bacterial disease.

Rapid viral diagnostic methods such as fluorescent antibody tests, enzyme-linked immunosorbent assay, and/or PCR should be performed on nasopharyngeal secretions to identify a viral etiology in high-risk patients, as well as for epidemiology or infection control. Diagnosis of a viral infection does not preclude the possibility of concomitant infection with other pathogens.

C. Imaging Studies
Chest radiographs frequently show perihilar streaking, increased interstitial markings, peribronchial cuffing, or patchy bronchopneumonia. Lobar consolidation or atelectasis may occur, however. Hyperinflation of the lungs may occur when involvement of the small airways is prominent.

Differential Diagnosis
The differential diagnosis of viral pneumonia is the same as for bacterial pneumonia. Patients with prominent wheezing may have asthma, airway obstruction caused by foreign body aspiration, acute bacterial or viral tracheitis.

Complications
Viral pneumonia or laryngotracheobronchitis may predispose the patient to subsequent bacterial tracheitis or pneumonia as immediate sequelae. Bronchiolitis obliterans or severe chronic respiratory failure may follow adenovirus pneumonia. The results of studies evaluating the development of asthma after a viral pneumonia are variable. Bronchiectasis, chronic hypersensitivity pneumonia and unilateral hyperlucent lung (Sawyer-James syndrome) may follow measles, adenovirus, and influenza pneumonias.
CHAPTER 19

Treatment

General supportive care for viral pneumonia does not differ from that for bacterial pneumonia. Patients can be quite ill and should be hospitalized according to the level of their illness. Because bacterial disease often cannot be definitively excluded, antibiotics may be indicated.

Patients at risk for life-threatening RSV infections (eg, those with BPD or other severe pulmonary conditions, congenital heart disease, or significant immunocompromise) should be hospitalized and ribavirin should be considered. Rapid viral diagnostic tests may be a useful guide for such therapy.

All children with influenza should be treated with the appropriate therapy for the specific type of influenza (A, B, H1N1). When available epidemiologic data indicate an active influenza infection in the community, rimantadine, amantadine hydrochloride, or oseltamivir phosphate should be considered early for high-risk infants and children who appear to be infected. Children with suspected viral pneumonia should be placed in respiratory isolation.

Prognosis

Although most children with viral pneumonia recover uneventfully, worsening asthma, abnormal pulmonary function or chest radiographs, persistent respiratory insufficiency, and even death may occur in high-risk patients such as newborns or those with underlying lung, cardiac, or immunodeficiency disease. Patients with adenovirus infection or those concomitantly infected with RSV and second pathogens such as influenza, adenovirus, cytomegalovirus, or P jiroveci also have a worse prognosis.

Prevention

The most effective preventions against RSV infection are proper handwashing techniques and reducing exposure to potential environmental risk factors. Prophylaxis with a monoclonal antibody (palivizumab) is effective in reducing the rate of hospitalization and associated morbidity in high-risk premature infants and those with chronic cardiopulmonary conditions.

Clinical Findings

A. Symptoms and Signs

The usual course of RSV bronchiolitis is 1–2 days of fever, rhinorrhea, and cough, followed by wheezing, tachypnea, and respiratory distress. Typically, the breathing pattern is shallow, with rapid respirations. Nasal flaring, cyanosis, retractions, and rales may be present, along with prolongation of the expiratory phase and wheezing, depending on the severity of illness. Some young infants present with apnea and few findings on auscultation but may subsequently develop rales, rhonchi, and expiratory wheezing.

B. Laboratory Findings and Imaging Studies

A nasal wash can be used to identify the causative pathogen but is not necessary to make the diagnosis of bronchiolitis. The peripheral white blood cell count may be normal or show a mild lymphocytosis. Chest radiographs are not indicated in children who have bilateral, symmetrical findings on examination, who are not in significant respiratory distress, and who do not have elevated temperature Chest radiograph findings are generally nonspecific and typically include hyperinflation, peribronchial cuffing, increased interstitial markings, and subsegmental atelectasis.

Complications

Bacterial superinfection is a rare complication of viral pneumonia. The results of studies investigating the risk for the subsequent development of chronic airway hyperreactivity (asthma) are variable. Bronchiolitis due to RSV infection contributes substantially to morbidity and mortality in children with underlying medical disorders, including chronic bronchiolitis.

BRONCHIOLITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► Clinical syndrome characterized by one or more of the following findings: coughing, tachypnea, labored breathing, and hypoxia.
► Irritability, poor feeding, vomiting.
► Wheezing and crackles on chest auscultation.

Bronchiolitis is the most common serious acute respiratory illness in infants and young children. The diagnosis of
lung disease of prematurity, CF, congenital heart disease, and immunodeficiency.

► **Treatment**

Although most children with RSV bronchiolitis are readily treated as outpatients, hospitalization is required in infected children with hypoxemia on room air, a history of apnea, moderate tachypnea with feeding difficulties, and marked respiratory distress with retractions. Children at high risk for hospitalization include infants (younger than 6 months), especially with any history of prematurity, and those with underlying chronic cardiopulmonary disorders. While in the hospital, treatment should include supportive strategies such as frequent suctioning and providing adequate fluids to maintain hydration. If hypoxemia is present, supplemental oxygen should be administered. There is no evidence to support the use of antibiotics in children with bronchiolitis unless there is evidence of an associated bacterial pneumonia. Bronchodilators and corticosteroids have not been shown to change the severity or the length of the illness in bronchiolitis and therefore are not recommended. Studies evaluating the effectiveness of hypertonic saline and heated high-flow oxygen therapy are ongoing.

Patients at risk for life-threatening RSV infections (eg, children younger than 24 months whose gestational age is less than 35 weeks, children younger than 24 months with other severe pulmonary conditions, congenital heart disease, neuromuscular disease, or significant immunocompromise) should be considered for RSV prophylaxis therapy. For more detail, refer to the American Academy of Pediatrics 2014 guidelines. High-risk patients with RSV bronchiolitis may need to be hospitalized and treated with ribavirin.

► **Prognosis**

The prognosis for most infants with acute bronchiolitis is very good. With improved supportive care and prophylaxis with palivizumab, the mortality rate among high-risk infants has decreased substantially.

**Mycoplasma pneumoniae** is a common cause of symptomatic pneumonia in older children although it may be seen in children younger than 5 years. Endemic and epidemic infection can occur. The incubation period is long (2–3 weeks), and the onset of symptoms is slow. Although the lung is the primary infection site, extrapulmonary complications sometimes occur.

► **Clinical Findings**

**A. Symptoms and Signs**

Fever, cough, headache, and malaise are common symptoms as the illness evolves. Although cough is usually dry at the onset, sputum production may develop as the illness progresses. Sore throat, otitis media, otitis externa, and bullous myringitis may occur. Rales and chest pain are frequently present on chest examination; decreased breath sounds or dullness to percussion over the involved area may be present.

**B. Laboratory Findings and Imaging Studies**

The total and differential white blood cell counts are usually normal. Enzyme immunoassay (EIA) and complement fixation are sensitive and specific for *M pneumoniae*. The cold hemagglutinin titer may be elevated during the acute presentation. A titer of 1:64 or higher supports the diagnosis. Acute and convalescent titers for *M pneumoniae* demonstrating a fourfold or greater rise in specific antibodies confirm the diagnosis. Diagnosis of mycoplasmal pneumonia by PCR is also available.

Chest radiographs usually demonstrate interstitial or bronchopneumonic infiltrates, frequently in the middle or lower lobes. Pleural effusions are extremely uncommon.

► **Complications**

Extrapulmonary involvement of the blood, central nervous system, skin, heart, or joints can occur. Direct Coombs–positive autoimmune hemolytic anemia, occasionally a life-threatening disorder, is the most common hematologic abnormality that can accompany *M pneumoniae* infection. Coagulation defects and thrombocytopenia can also occur. Cerebral infarction, meningoencephalitis, Guillain-Barré syndrome, cranial nerve involvement, and psychosis all have been described. A wide variety of skin rashes, including erythema multiforme and Stevens-Johnson syndrome, can occur. Myocarditis, pericarditis, and a rheumatic fever–like illness can also occur.

► **Treatment**

Antibiotic therapy with a macrolide for 7–10 days may shorten the course of illness. Ciprofloxacin is a possible alternative. Supportive measures, including hydration, antipyretics, and bed rest, are helpful.
Prognosis

In the absence of the less common extrapulmonary complications, the outlook for recovery is excellent.

ASPIRATION PNEUMONIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► History of recurrent aspiration or an aspiration event.
► New-onset respiratory distress, oxygen requirement, or fever, after the aspiration.
► Any new-onset respiratory distress or increase in oxygen requirement in a child with known aspiration.
► Focal findings on physical examination.

Patients whose anatomic defense mechanisms are impaired are at risk of aspiration pneumonia (Table 19–6). Acute disease is commonly caused by bacteria present in the mouth (especially gram-negative anaerobes). Chronic aspiration often causes recurrent bouts of acute febrile pneumonia. Aspiration pneumonia may be acute or chronic, but is more common in children with other underlying medical conditions (see Table 19–6). An acute aspiration event may lead to a typical pneumonia syndrome with fever, asymmetrical auscultation findings, and asymmetric imaging findings.

Chronic aspiration pneumonitis is more indolent and can cause chronic respiratory symptoms of “rattling,” cough or wheezing, chronic chest infiltrates, bronchiectasis, or failure to thrive.

Clinical Findings

A. Symptoms and Signs

Acute onset of fever, cough, respiratory distress, or hypoxemia in a patient at risk suggests acute aspiration pneumonia. Chest physical findings, such as rales, rhonchi, or decreased breath sounds, may initially be limited to the lung region into which aspiration occurred. Although any region may be affected, the right side—especially the right upper lobe in the supine patient—is commonly affected. In patients with chronic aspiration “chest rattling” is often described by parents. Generalized rales and wheezing may also be present.

B. Laboratory Findings and Imaging Studies

Chest radiograph abnormalities can vary widely. They may reveal lobar consolidation or atelectasis and focal or generalized alveolar or interstitial infiltrates. In some patients with chronic aspiration, perihilar infiltrates with or without bilateral air trapping may be seen. In patients with severe acute illness, a bacteriologic diagnosis should be made (see section Diagnosis of Respiratory Tract Infections). In children with acute or chronic aspiration pneumonitis, BAL specimen may be considered to diagnose bacterial infection.

In patients with chronic aspiration pneumonitis, attempts should be made to document aspiration. Video fluoroscopic swallow study, also known as modified barium swallow, is typically performed to evaluate the swallow. Fiberoptic endoscopic examination of swallowing (FEES) is done at specialty centers to directly visualize the swallow using a fiberoptic laryngoscope. Radionuclide studies have low sensitivity to diagnosis aspiration. Biomarkers such as lipid-laden macrophages obtained from BAL samples also have low sensitivity and specificity. The role of gastroesophageal reflux in chronic aspiration is difficult to determine. An esophageal pH impedance study may help establish the diagnosis of gastroesophageal reflux. Rigid bronchoscopy in infants or flexible bronchoscopy in older children can be used to identify anatomic abnormalities such as tracheal cleft and tracheoesophageal fistula. Complications such as empyema or lung abscess may complicate acute aspiration pneumonia, while chronic aspiration may also result in bronchiectasis. If there is clinical concern, chest computed tomography can better delineate these complications.

Differential Diagnosis

In the acutely ill patient, bacterial and viral pneumonias should be considered. In the chronically ill patient, the differential diagnosis may include disorders causing recurrent
pneumonia (eg, immunodeficiencies, ciliary dysfunction, or foreign body), chronic wheezing, or interstitial lung disorders (see the next section), depending on the presentation.

**Treatment**

Aspiration pneumonia leads to a chemical pneumonitis and, in some cases supportive treatment is the recommended therapy. Antimicrobial therapy for patients who are acutely ill from aspiration pneumonia includes coverage for anaerobic organisms. In general, clindamycin is appropriate initial coverage.

Treatment of chronic aspiration pneumonia may include the following: surgical correction of anatomic abnormalities; thickening of liquids taken by mouth, swallowing therapy, improved oral hygiene, inhaled corticosteroids, and chest physiotherapy. In patients with compromise of the central nervous system, exclusive feeding by gastrostomy may be required. Gastroesophageal reflux, if present in these patients, may require surgical correction. Because of the widespread causes and consequences of chronic aspiration, multidisciplinary subspecialty management is often recommended.

**PNEUMONIA IN THE IMMUNOCOMPROMISED HOST**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

The nature of the immunocompromised state may help predict etiology of pulmonary infection.

Compromised immune function occurs following solid organ or hematopoietic stem cell transplantation, in patients with congenital immune deficits, and in patients receiving cancer chemotherapy or other immunosuppressant therapy, including chronic corticosteroids.

Pulmonary infection, which is the most common infection in these patients, can present as focal pneumonia or ILD. The underlying cause of the immunocompromised state often determines the spectrum of infectious agents responsible for disease (see also Chapter 33). Pneumonia in an immunocompromised host may be due to any common community-acquired bacteria or less common pathogens such as opportunistic fungi, *Toxoplasma gondii*, *P jiroveci*, anaerobic bacteria, *Nocardia* species, *Legionella pneumophila*, mycobacteria, and viruses. Multiple organisms are commonly isolated in culture and disseminated disease is possible.

**Clinical Findings**

**A. Symptoms and Signs**

Patients often present with subtle signs such as mild cough, tachypnea, or low-grade fever that can rapidly progress to high fever, respiratory distress, and hypoxemia or chILD syndrome. An obvious portal of infection, such as an intravascular catheter, may predispose to bacterial or fungal infection via hematogenous spread.

**B. Laboratory Findings and Imaging Studies**

Fungal, parasitic, or bacterial infection, especially with antibiotic-resistant bacteria, should be suspected in the neutropenic child. Cultures of peripheral blood and through intravascular catheters, sputum, tracheobronchial secretions, nasopharynx or sinuses, pleural fluid, biopsied lymph nodes, bone marrow, or skin lesions should be considered and obtained as soon as infection is suspected. Serum (1, 3)-β-d-glucan assays and serum and bronchoalveolar lavage (BAL) galactomannan assays for invasive pulmonary fungal disease are being used in some centers. Urine can be tested for typical pathogens and *Legionella* urinary antigens.

Invasive methods are commonly required to make a diagnosis. Appropriate samples should be obtained soon after a patient with pneumonia fails to respond to initial treatment. The results of these procedures usually lead to important changes in empiric therapy. Sputum is often unavailable in the young child. BAL frequently detects one or more organisms and should be done early in evaluation. The combined use of a wash, brushing, endobronchial biopsy, and lavage has a high yield. In patients with rapidly advancing, or more peripheral disease, lung biopsy becomes more urgent. The morbidity and mortality of this procedure can be reduced by a surgeon skilled in video-assisted thoracoscopic surgical (VATS) techniques.

Because of the multiplicity of organisms that may cause disease, a comprehensive set of studies should be done on lavage and biopsy material. These consist of rapid diagnostic studies including culture, PCR, and antigen detection for viruses and rapid fluorescent antibody studies for *P jiroveci* and *Legionella*; Gram, acid-fast, and fungal stains; cytologic examination for viral inclusions; and cultures for anaerobic and aerobic bacteria, fungi, mycobacteria, and *Legionella*.

Chest radiographs and high-resolution CT scans may be useful in identifying the pattern and extent of disease. In early *P jiroveci* pneumonia, dyspnea and hypoxemia may be marked despite minimal radiographic abnormalities. Distinctive radiographic findings such as the halo sign can be seen in aspergillosis.
CHAPTER 19

Differential Diagnosis

The organisms causing disease vary with the type of immunocompromise present. For example, the splenectomized or sickle cell disease patient may be overwhelmed by infection with encapsulated bacteria. The child with HIV/AIDS or receiving immunosuppressant therapy or chemotherapy is more likely to have *P jiroveci* infection. The febrile neutropenic child who has been receiving adequate doses of intravenous broad-spectrum antibiotics or systemic steroid therapy may have fungal disease. The key to diagnosis is to consider all possibilities of infection.

Depending on the form of immunocompromise, perhaps only half to two-thirds of new pulmonary infiltrates in such patients represent infection. The remainder are caused by pulmonary toxicity of radiation, chemotherapy, or other drugs; pulmonary disorders, including hemorrhage, embolism, atelectasis, or aspiration; idiopathic pneumonia syndrome or acute respiratory distress syndrome in bone marrow transplant patients; recurrence or extension of primary malignant growths or immunologic disorders; transfusion reactions, leukostasis, or tumor cell lysis; or ILD, such as lymphocytic interstitial pneumonitis with HIV infection.

Complications

Necrotizing pneumonia, lung abscess, and parapneumonic effusions can develop. Progressive respiratory failure, shock, multiple organ damage, disseminated infection, and death commonly occur in the infected immunocompromised host.

Treatment

Early use of broad-spectrum intravenous antibiotics is indicated in febrile, neutropenic, or immunocompromised children. Trimethoprim-sulfamethoxazole (for *Pneumocystis*) and macrolides (for *Legionella*) are also indicated early in the treatment of immunocompromised children before an organism is identified. Further, targeted therapy should be based on studies of specimens obtained from BAL or lung biopsy. Recent data suggest that use of noninvasive ventilation strategies early in the course of pulmonary insufficiency or respiratory failure may decrease mortality.

Prognosis

Prognosis is based on the severity of the underlying immunocompromise, appropriate early diagnosis and treatment, and the infecting organisms. Intubation and mechanical ventilation have been associated with high mortality rates, especially in hematopoietic stem cell transplant patients.

LUNG ABSCESS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- High fever, malaise, and weight loss in the setting of pneumonia.
- Chest radiographs and CT scans usually reveal lung cavities, often with air-fluid levels.

Pathogenesis

Lung abscesses are thick-walled cavities that form from inflammation and central necrosis following an initial pulmonary infection. A lung abscess occurs in a previously well child or one prone to aspiration and also occur in children with or in children with immunosuppression or underlying lung or systemic disease. Lung abscesses may also occur via embolic spread. Organisms such as *S aureus* and other staphylococci, *S pneumoniae*, and streptococci more commonly affect the healthy host, while anaerobic and gram-negative organisms as well as *Nocardia*, mycobacteria, *Legionella* species, and fungi (*Candida* and *Aspergillus*) should be considered in the immunocompromised host or in patients not responding to treatment.

Clinical Findings

A. Symptoms and Signs

Symptoms and signs referable to the chest may or may not be present. High fever, malaise, and weight loss are often present. In infants, evidence of respiratory distress can be present.

B. Laboratory Findings and Imaging Studies

Elevated peripheral white blood cell count with a neutrophil predominance or an elevated erythrocyte sedimentation rate or C-reactive protein may be present. Blood cultures are rarely positive except in the immunocompromised patient.

Chest radiographs usually reveal single or multiple thick-walled lung cavities. Air-fluid levels can be present.
Local compressive atelectasis, pleural thickening, or adenopathy may also occur. Chest CT scan may provide better localization and understanding of the lesions.

In patients producing sputum, stains, and cultures may provide the diagnosis. Direct percutaneous aspiration of material for stains and cultures should be considered although complications can occur.

**Differential Diagnosis**

Loculated pyopneumothorax, neoplasms, plasma cell granuloma, and infected congenital cysts and sequestrations should be considered. Pneumatoceles, non–fluid-filled cysts, are common in children with empyema and usually resolve over time.

**Complications**

Although complications due to abscesses are now rare, mediastinal shift, tension pneumothorax, and spontaneous rupture can occur. Diagnostic maneuvers such as radiology-guided lung puncture to drain and culture the abscess may also cause a pneumothorax or a bronchopulmonary fistula.

**Treatment**

Because of the risks of lung puncture, uncomplicated abscesses are frequently conservatively treated in the immune competent host with appropriate broad-spectrum intravenous antibiotics. Additional coverage for anaerobic gram-negative organisms and fungi should be provided for others. Prolonged therapy with 2–3 weeks of intravenous antibiotics followed by oral therapy may be required. Attempts to drain abscesses via bronchoscopy have caused life-threatening airway compromise. Surgical drainage or lobectomy is occasionally required, primarily in immunocompromised patients. However, such procedures may themselves cause life-threatening complications.

**Prognosis**

Although radiographic resolution may be very slow (6 weeks–5 years), resolution occurs in most patients without risk factors for lower respiratory tract infections or loss of pulmonary function. In the immunocompromised or medically complex host, the outlook depends on the underlying disorder.

**BRONCHIOлитIS OBLITERANS**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Persistent symptoms of airway obstruction 8 weeks after the resolution of a lower respiratory tract infection.
- Chest CT shows a mosaic pattern of hyperinflation and vascular attenuation.

Bronchiolitis obliterans is a rare chronic obstructive lung disease characterized by complete obliteration of the small airways following a severe insult. The most common form in children is post-infectious, following a lower airway tract infection with adenovirus, although influenza, rubeola, Bordetella, and Mycoplasma are also implicated. Other causes include connective tissue diseases, chronic aspiration, Stevens-Johnson syndrome, post-transplantation (lung or bone marrow) and inhalational injury. Many cases of bronchiolitis obliterans are idiopathic. Mechanical ventilation for severe adenoviral respiratory infection is a strong risk factor for development of bronchiolitis obliterans.

**Clinical Findings**

**A. Symptoms and Signs**

Persons with bronchiolitis obliterans usually experience dyspnea, coughing, and exercise intolerance. This diagnosis should be considered in children with persistent cough, wheezing, crackles, or hypoxemia lasting longer than 60 days following a lower respiratory tract infection.

**B. Laboratory Findings and Imaging Studies**

Chest radiograph abnormalities include evidence of heterogeneous air trapping and airway wall thickening. Traction bronchiectasis can occur as the disease progresses. Classic findings on high-resolution chest CT include a mosaic perfusion pattern, vascular attenuation, and central bronchiectasis. This finding along with pulmonary function testing showing airway obstruction unresponsive to bronchodilators may be diagnostic in patients with the appropriate clinical history. Although not typically required for diagnosis, ventilation-perfusion scans may show a pattern of ventilation and perfusion mismatch. Pulmonary angiograms reveal decreased vasculature in involved lung, and bronchograms show marked pruning of the bronchial tree.

**Differential Diagnosis**

Poorly treated asthma, CF, and BPD must be considered in children with persistent airway obstruction. A trial of
medications (including bronchodilators and corticosteroids) may help determine the reversibility of the process when the primary differential is between asthma and bronchiolitis obliterans. Others without classic findings on CT scan and lung function testing may require a lung biopsy.

**Complications**

Sequelae of bronchiolitis obliterans include persistent airway obstruction, recurrent wheezing, bronchiectasis, chronic atelectasis, recurrent pneumonia, and unilateral hyperlucent lung syndrome.

**Treatment**

Supportive care, including supplemental oxygen for hypoxemia, routine vaccination, avoidance of environmental irritant exposure, exercise, and nutritional support should be provided. Ongoing airway damage due to problems such as aspiration should be prevented. Inhaled bronchodilators (β-agonists and anticholinergic) may reverse airway obstruction if the disease has a reactive component. Systemic corticosteroids may help reverse the obstruction or prevent ongoing damage; monthly pulse-dose corticosteroids will reduce the risk of adverse effects associated with long-term corticosteroids. Antibiotics should be used as indicated for pneumonia. Azithromycin has been shown to have therapeutic benefit in bronchiolitis obliterans syndrome after lung transplantation, providing rationale for a trial of this medication for bronchiolitis obliterans. Lung transplant may be an option for patients with severe, progressive disease.

**Prognosis**

Prognosis depends in part on the underlying cause as well as the age of onset. Postinfectious bronchiolitis obliterans tends to be nonprogressive with low mortality and the possibility of slow improvement. Conversely, posttransplantation or Stevens-Johnson syndrome related-bronchiolitis obliterans may have a rapidly progressive course leading to death or need for lung transplantation.

**Children’s Interstitial Lung Disease Syndrome**

**Essentials of Diagnosis & Typical Features**

- Patients can present at any age.
- Pathology can be in the airway, airspace, and/or interstitium.
- Diverse group of rare pulmonary disorders.
- Diagnosis: In the absence of known causes of lung disease (cystic fibrosis, primary ciliary dyskinesia, bronchopulmonary dysplasia, aspiration, etc.), patients present with at least three of the following:
  - Respiratory symptoms
  - Respiratory signs
  - Hypoxemia
  - Diffuse abnormality on chest imaging

Children’s Interstitial and diffuse Lung Disease (chILD) syndrome is a constellation of signs and symptoms and not a specific diagnosis. Once recognized, chILD syndrome should elicit a search for a more specific chILD diagnosis. Disorders with similar presentations such as CF, cardiac disease, asthma, acute infection, immunodeficiency, neuromuscular disease, scoliosis, thoracic cage abnormality, chronic lung disease of prematurity, and aspiration must be excluded. chILD presents differently than ILD in adults (ie, idiopathic pulmonary fibrosis) and there are a number of specific forms of chILD that are seen in infants but not adults.

**Clinical Findings**

**A. Symptoms and Signs**

chILD syndrome may present acutely in infants and young children with respiratory failure or insidiously with respiratory symptoms and signs such as cough, exercise intolerance, clubbing, dyspnea, tachypnea, retractions, hypoxemia, barrel chest, and failure to thrive.

**B. Laboratory Findings**

Initial evaluations should be directed at ruling out alternative causes and may include PFTs; skin tests; complete blood count and erythrocyte sedimentation rate; sweat chloride test for CF; cardiac evaluation such as an electrocardiogram and/or echocardiogram; serum immunoglobulins and other immunologic evaluations.
C. Imaging Studies

Chest radiographs are normal in up to 10%–15% of patients. Specific chILD disorders (eg, bronchiolitis obliterans and neuroendocrine cell hyperplasia of infancy) can be diagnosed using controlled volume inspiratory and expiratory high-resolution CT. Videofluoroscopic swallow studies will evaluate if the patient is at risk for aspiration.

D. Special Tests

Pulmonary function testing is typically abnormal in chILD. Depending on the specific type of chILD, PFTs may show (1) a restrictive pattern of decreased lung volumes, compliance, and carbon monoxide diffusing capacity, (2) an obstructive pattern with hyperinflation, or (3) a mixed obstructive-restrictive pattern. Six-minute walk may demonstrate desaturation and distance may be reduced. Exercise-induced or nocturnal hypoxemia may be the earliest detectable abnormality of lung function in children.

Bronchoscopy is performed to exclude anatomic abnormalities and obtain BAL for microbiologic and cytologic testing. Commercial genetic testing is available for some forms of chILD, including surfactant dysfunction mutations (SFTPB, SFTPC, ABCA3, and NKX2.1), alveolar capillary dysplasia (FOXF1), pulmonary alveolar proteinosis (GMCSF receptor mutations or autoantibodies), pulmonary hemorrhage (COPA). Novel genetic causes of chILD are rapidly evolving. Whole exome and whole genome sequencing will likely discover many additional genetic etiologies of chILD. Genetic mutations inform prognosis, potential therapeutics, and genetic counseling. Some genotype-phenotype correlations exist.

Lung biopsy may provide definitive diagnosis, especially when evaluated by pathologists experienced in chILD. Video-assisted thoracoscopically lung biopsies are preferred when possible. Patients benefit from evaluation at a chILD center of expertise with pediatric pulmonologists, pathologists, and radiologists together evaluating the patient for a diagnosis.

Differential Diagnosis

Many disorders can present similar to chILD syndrome: cystic fibrosis cardiac disease, asthma, acute infection, immunodeficiency, neuromuscular disease, scoliosis, thoracic cage abnormality, chronic lung disease of prematurity, and aspiration.

Complications

Complications from chILD include being behind in school, failure to thrive, respiratory insufficiency, respiratory failure, and pulmonary hypertension. Mortality and morbidity can be significant and vary by specific diagnosis.

Treatment

All patients should be evaluated for comorbidities such as pulmonary hypertension with regular echocardiograms, aspiration, failure to thrive, and respiratory insufficiency. All vaccines should be provided, including annual influenza vaccine, palivizumab in infancy, and pneumococcal polysaccharide vaccine. Nutritional and respiratory support should be provided as appropriate to allow for optimal growth and development. Advice regarding avoidance of environmental irritant exposure (recreational and occupational) should be provided. Treatment for specific forms of chILD is disease specific and largely based on expert opinion, case reports, and small case series. Children with ILD should be evaluated and cared for by an experienced multidisciplinary team. The chILD Family Foundation can provide further supportive resources for families (http://www.childfoundation.us).

Prognosis

Prognosis varies by chILD diagnosis.

HYPERSENSITIVITY PNEUMONITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

History of recurrent respiratory symptoms, especially exercise intolerance, cough, weight loss, and fever.

History of exposure to an inhaled organic particle (birds) or low molecular weight chemicals.

Hypersensitivity pneumonitis, or extrinsic allergic alveolitis, is a T-cell–mediated disease involving the peripheral airways, interstitium, and alveoli and presents as a distinct form of chILD. Disease is triggered by an environmental exposure and a host reaction. Viral infections, smoking, and genetic polymorphisms likely modify disease. Both acute
and chronic forms may occur. In children, the most common forms are caused by exposure to birds or bird droppings (eg, pigeons, parakeets, parrots, or doves) also known as “bird fancier’s lung.” Intensity, duration, and genetic predisposition are all important factors. However, inhalation of almost any organic dust (moldy hay, compost, logs or tree bark, sawdust, or aerosols from humidifiers or hot tubs) can cause disease. Methotrexate-induced hypersensitivity has also been described in a child with juvenile rheumatoid arthritis. Hot tub lung can be caused by exposure to aerosolized *Mycobacterium avium* complex. A high level of suspicion and a thorough history with attention to environmental exposures are required for diagnosis.

**Clinical Findings**

**A. Symptoms and Signs**

Episodic cough and fever can occur with acute exposures. Chronic exposure results in weight loss, fatigue, hypoxemia, and dyspnea. Physical examination findings include crackles, loud P2, and clubbing.

**B. Laboratory Findings and Imaging studies**

Acute exposure may be followed by polymorphonuclear leukocytosis with eosinophilia and evidence of airway obstruction on pulmonary function testing. Chronic disease results in a restrictive picture on lung function tests.

Serum precipitins (precipitating IgG antibodies) to the organic materials that contain avian proteins or fungal or bacterial antigens may be detected. Ideally, to identify avian proteins, the patient’s sera should be tested with antigens from droppings of the suspected species of bird. However, exposure may invoke precipitins without causing disease.

Chest radiograph findings are variable and may include normal lung fields, air-space consolidation, and nodular or reticulonodular patterns. High-resolution CT of the chest often shows centrilobular nodules, ground-glass opacities, and air-trapping. Pulmonary fibrosis is seen in chronic disease. Lymphocytosis on BAL may be suggestive.

Lung biopsy may be necessary if other diagnostic testing is inconclusive. Histopathology is characterized by bronchiolocentric interstitial inflammation with lymphocyte predomination, interstitial nonnecrotizing, poorly formed granulomas, and intraalveolar foci of organizing pneumonia.

**Differential Diagnosis**

Patients with mainly acute symptoms must be differentiated from those with atopic asthma. Patients with chronic symptoms must be distinguished from those with collagen-vascular, immunologic, or other forms of chILD. In adults, idiopathic pulmonary fibrosis is a diagnosis of exclusion.

**Complications**

Prolonged exposure to offending antigens may result in pulmonary hypertension due to chronic hypoxemia, irreversible restrictive lung disease and pulmonary fibrosis.

**Treatment & Prognosis**

Complete elimination of exposure to the offending antigens is required. Corticosteroids may hasten recovery. With appropriate early diagnosis and identification and avoidance of offending antigens, the prognosis is excellent.

---

**DISEASES OF THE PULMONARY CIRCULATION**

**PULMONARY HEMORRHAGE**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- **History of hemoptysis.**
- **New-onset respiratory distress, oxygen requirement, or fatigue with evidence of infiltrate by chest imaging and blood in the tracheal aspirate.**

Pulmonary hemorrhage can be caused by a spectrum of disorders affecting the large and small airways and alveoli. It can occur as an acute or chronic process. If pulmonary hemorrhage is subacute or chronic, hemosiderin-laden macrophages can be found in tracheal aspirates 48–72 hours after the bleeding begins. Many cases are secondary to bacterial, mycobacterial, parasitic, viral, or fungal infections (such as the toxigenic mold *Stachybotrys chartarum*). Lung abscess, bronchiectasis (from CF or other causes), foreign body, coagulopathy (often with overwhelming sepsis), or elevated pulmonary venous pressure (secondary to congestive heart failure, anatomic heart lesions, or ascent to high altitude) may also cause pulmonary hemorrhage. Other causes include lung contusion from trauma, pulmonary embolus with infarction, arteriovenous fistula or telangiectasias, autoimmune vasculitis, hypersensitivity pneumonitis pulmonary sequestration, agenesis of a single pulmonary artery, and esophageal duplication or bronchogenic cyst. In children, pulmonary hemorrhage due to airway tumors (eg, bronchial adenoma) is very rare.
Hemorrhage involving the alveoli is termed diffuse alveolar hemorrhage. This may be idiopathic, drug-related or may occur in Goodpasture syndrome, rapidly progressive glomerulonephritis, and systemic vasculitides (often associated with such collagen-vascular diseases as systemic lupus erythematosus, rheumatoid arthritis, Wegener granulomatosis, polyarteritis nodosa, Henoch-Schönlein purpura, and Behçet disease). Idiopathic pulmonary hemosiderosis refers to the accumulation of hemosiderin in the lung, especially in alveolar macrophages, as a result of chronic or recurrent hemorrhage (usually from pulmonary capillaries) that is not associated with the previously listed causes. Children and young adults are mainly affected, with the age at onset ranging from 6 months to 20 years.

**Clinical Findings**

**A. Symptoms and Signs**

Large airway hemorrhage presents with hemoptyisis and symptoms of the underlying cause, such as infection, foreign body, or bronchiectasis in CF. Hemoptyisis from larger airways is often bright red or contains clots. Children with diffuse alveolar hemorrhage may present with massive hemoptyisis, marked respiratory distress, stridor, or a pneumonia-like syndrome. However, most patients with diffuse alveolar hemorrhage and idiopathic pulmonary hemosiderosis present with nonspecific respiratory symptoms (cough, tachypnea, and retractions) with or without hemoptyisis, poor growth, and fatigue. Fever, abdominal pain, and chest pain may also be reported. Jaundice and hepatosplenomegaly may be present with chronic bleeding. Physical examination often reveals decreased breath sounds, rales, rhonchi, or wheezing and digital clubbing.

**B. Laboratory Findings and Imaging Studies**

Laboratory studies depend on the cause of hemorrhage. When gross hemoptyisis is present, large airway bronchiectasis, epistaxis, foreign body, and arteriovenous malformations should be considered. Flexible bronchoscopy and imaging (MRI or CT-assisted angiography) can be used to localize the site of bleeding. Alveolar bleeding with hemoptyisis is often frothy and pink. Long-standing idiopathic pulmonary hemorrhage may cause iron deficiency anemia and heme-positive sputum. Nonspecific findings may include lymphocytosis and an elevated erythrocyte sedimentation rate. Peripheral eosinophilia is present in up to 25% of patients. Chest radiographs may demonstrate perihilar infiltrates, fluffy alveolar infiltrates with or without atelectasis, and mediastinal adenopathy. Pulmonary function testing generally reveals restrictive impairment, with low lung volumes, poor compliance, and an increased diffusion capacity. Hemosiderin-laden macrophages are found in the BAL fluid and tracheal aspirates. The diagnostic usefulness of lung biopsy is controversial.

Patients with diffuse alveolar hemorrhage with an underlying systemic disease may need a lung biopsy. In patients with systemic lupus erythematosus, granulomatosis and polyangiitis (formerly called Wegener granulomatosis), and occasionally Goodpasture syndrome diffuse alveolar hemorrhage can occur in the setting of necrotizing pulmonary capillaritis. Lung biopsy reveals alveolar septa infiltrated with neutrophils, edema, or necrosis in addition to alveolar hemorrhage. Idiopathic pulmonary hemosiderosis is a mild form of capillaritis associated with focal or diffuse alveolar hemorrhage. Other causes of pulmonary hemosiderosis include collagen-vascular disease, immune-mediated vasculitis, and pulmonary fibrosis must be ruled out to diagnose idiopathic pulmonary hemosiderosis. Lung biopsy often shows immune-mediated capillaritis in the absence of an identifiable serologic marker. Serologic studies such as circulating antineutrophilic cytoplasmic autoantibodies for Wegener granulomatosis, perinuclear antineutrophilic cytoplasmic autoantibodies for microscopic polyangiitis, antinuclear antibodies for systemic lupus erythematosus, and anti–basement membrane antibodies for Goodpasture syndrome should be obtained. α1-Antitrypsin deficiency should also be considered.

Cow’s milk–induced pulmonary hemosiderosis (Heiner syndrome) can be confirmed by high titers of serum precipitins to multiple constituents of cow’s milk and positive intradermal skin tests to cow’s milk proteins. Improvement after eliminating cow’s milk supports the diagnosis.

**Differential Diagnosis**

Bleeding from the nose or mouth can present as hemoptyisis. Therefore, a complete examination of the nose and mouth is required before confirming the diagnosis of intrapulmonary bleeding. Hematemesis can also be confused with hemoptyisis; confirming that the blood was produced after coughing and not with emesis should also be part of the initial evaluation. A complete past medical history including underlying systemic illness and cardiovascular anomalies may direct the search for the site of respiratory bleeding.

**Treatment**

Therapy should be aimed at direct treatment of the underlying disease. In severe bleeding, intubation with application of positive pressure during mechanical ventilation and/or endotracheal administration of epinephrine may help attenuate bleeding. Patients with CF or bronchiectasis from other causes who develop massive (> 240 mL) or recurrent hemoptyisis, may require bronchial artery embolization. Although its use requires anticoagulation, extracorporal life support has resulted in the survival of children with severe pulmonary hemorrhage. For chronic bleeding, supportive measures, including iron therapy, supplemental oxygen, and...
blood transfusions, may be needed. A diet free of cow’s milk should be tried in infants. Systemic corticosteroids have been used for various causes of diffuse alveolar hemorrhage and have been particularly successful in those secondary to collagen-vascular disorders and vasculitis. Case reports have been published describing the variable effectiveness of steroids, chloroquine, cyclophosphamide, and azathioprine for idiopathic pulmonary hemosiderosis.

**Prognosis**

The outcome of pulmonary hemorrhage depends on the cause of the bleeding and how much blood has been lost. The course of idiopathic pulmonary hemosiderosis is variable, characterized by a waxing and waning course of intermittent intrapulmonary bleeds and the gradual development of pulmonary fibrosis. The severity of the underlying renal disease influences mortality associated with Goodpasture syndrome and Wegener granulomatosis. Diffuse alveolar hemorrhage is considered a lethal pulmonary complication of systemic lupus erythematosus.

**Clinical Findings**

**A. Symptoms and Signs**

Pulmonary embolism usually presents as an acute onset of dyspnea and tachypnea. Heart palpitations, pleuritic chest pain, and a sense of impending doom may be reported. Hemoptyis is rare, but may occur along with splinting, cyanosis, and tachycardia. Massive emboli may be present with syncope and cardiac arrhythmias. Physical examination is usually normal (except for tachycardia and tachypnea) unless the embolism is associated with an underlying disorder. Mild hypoxemia, rales, focal wheezing, or a pleural friction rub may be found.

**B. Laboratory Findings and Imaging Studies**

Radiographic findings may be normal, but a peripheral infiltrate, small pleural effusion, or elevated hemidiaphragm can be present. If the emboli are massive, differential blood flow and pulmonary artery enlargement may be appreciated. The electrocardiogram is usually normal unless the pulmonary embolus is massive. Echocardiography is useful in detecting the presence of a large embolus in the great vessels. A negative D-dimer has a more than 95% negative predictive value for an embolus, but has poor specificity. Ventilation-perfusion scans show localized areas of ventilation without perfusion.

Spiral CT with contrast may be helpful, but pulmonary angiography is the gold standard. A recent case series suggests that bedside chest ultrasound may aid in diagnosing pulmonary emboli, particularly in critically ill children. Further evaluation may include Doppler ultrasound studies of the legs to search for deep venous thrombosis. Coagulation studies, including assessments of antithrombin III, fibrinogen, antiphospholipid antibodies, homocystine, coagulation regulatory proteins (proteins C and S, and factor V Leiden), and the prothrombin G20210A mutation are abnormal in up to 70% of pediatric patients with pulmonary embolism.

**Treatment**

Acute treatment includes supplemental oxygen, and anticoagulation. Current recommendations include heparin therapy to maintain an activated partial thromboplastin time of greater than 1.5 times the control value for the first 24 hours. Urokinase or tissue plasminogen activator can be used to help dissolve the embolus. These therapies should be followed by warfarin therapy for at least 6 weeks with an international normalized ratio (INR) greater than 2.

---

**PULMONARY EMBOLISM**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Acute onset dyspnea and tachypnea.
- Evidence of embolism on chest imaging.

Pulmonary embolism is a rare, but severe cause of respiratory distress in children. Etiologies include: sickle cell anemia (as part of the acute chest syndrome), malignancy, rheumatic fever, infective endocarditis, bone fracture, dehydration, polycythemia, nephrotic syndrome, atrial fibrillation, and other conditions. Many children with pulmonary emboli referred for hematology evaluation have coagulation regulatory protein abnormalities and antiphospholipid antibodies. Emboli result in clinical signs and symptoms in proportion to the severity of pulmonary vascular obstruction. In children, tumor emboli are a more common cause of massive pulmonary embolism than embolization from a lower extremity deep venous thrombosis.
PULMONARY EDEMA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Dyspnea and oxygen requirement.
- Evidence of pulmonary edema on chest imaging.

Pathogenesis

Pulmonary edema is excessive accumulation of extravascular fluid in the lung. This occurs when fluid is filtered into the lungs faster than it can be removed, leading to changes in lung mechanics such as decreased lung compliance, worsening hypoxemia from ventilation-perfusion mismatch, bronchial compression, and if advanced, decreased surfactant function. There are two basic types of pulmonary edema: increased pressure (cardiogenic or hydrostatic) and increased permeability (noncardiogenic or primary). Hydrostatic pulmonary edema is usually due to excessive increases in pulmonary venous pressure, in the setting of congestive heart failure. Postobstructive pulmonary edema occurs when airway occlusion (or its sudden relief) causes a sudden drop in airway pressure which leads to increased venous return and decreased left heart blood flow. These changes result in elevated hydrostatic pressures and transudation of fluid from the pulmonary capillaries to the alveolar space.

In contrast, many lung diseases, especially acute respiratory distress syndrome, are characterized by the development of pulmonary edema secondary to changes in permeability due to injury at the alveolar-capillary interface. In this setting, pulmonary edema occurs independently of the elevations of pulmonary venous pressure.

Clinical Findings

A. Symptoms and Signs

Cyanosis, tachypnea, tachycardia, and respiratory distress are commonly present. Physical findings include rales, diminished breath sounds, and (in young infants) expiratory wheezing. More severe disease is characterized by progressive respiratory distress with marked retractions, dyspnea, and severe hypoxemia.

B. Imaging Studies

Chest radiographic findings depend on the cause of the edema. Pulmonary vessels are prominent, often with diffuse interstitial or alveolar infiltrates. Heart size is usually normal in permeability edema but enlarged in hydrostatic edema.

Treatment

Although specific therapy depends on the underlying cause, supplemental oxygen therapy and ventilator support may be indicated. Diuretics, digoxin, and vasodilators may be indicated for congestive heart failure along with restriction of salt and water. Loop diuretics, such as furosemide, are primarily beneficial because they increase systemic venous capacitance, not because they induce diuresis. Improvement can even be seen in anuric patients. Recommended interventions for pulmonary edema include reduction of vascular volume and maintenance of the lowest central venous or pulmonary arterial wedge pressure possible without sacrificing cardiac output or causing hypotension (see following discussion). β-Adrenergic agonists such as terbutaline have been shown to increase alveolar clearance of lung water, perhaps through the action of a sodium-potassium channel pump. Maintaining normal albumin levels and a hematocrit concentration above 30 maintains the filtration of lung liquid toward the capillaries.

High-altitude pulmonary edema (HAPE) occurs when susceptible individuals develop noncardiogenic edema after rapid ascent to altitudes above 3000 m. HAPE in children may be variable. Oxygen therapy and prompt descent are the cornerstones of therapy for this illness.

Congenital Pulmonary Lymphangiectasia

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Respiratory distress and oxygen requirement at birth.
- Diagnosed by chest CT showed dilated lymphatic suggested by interstitial prominence.

Congenital pulmonary lymphangiectasia consists of dilated subpleural and interlobular lymphatic channels, often as part of a generalized lymphangiectasis (in association with obstructive cardiovascular lesions—especially total anomalous pulmonary venous return) or as an isolated idiopathic lesion. Pathologically, the lung appears firm, bulky, and
noncompressible, with prominent cystic lymphatics visible beneath the pleura. On cut section, dilated lymphatics are present near the hilum, along interlobular septa, around bronchovascular bundles, and beneath the pleura. Histologically, dilated lymphatics have a thin endothelial cell lining overlying a delicate network of elastin and collagen.

**Clinical Findings**

Congenital pulmonary lymphangiectasia is a rare, usually fatal, disease that generally presents as acute, severe, or persistent respiratory distress at birth. There are reports of children developing symptoms in the first few months of life and others report diagnosis later in childhood. Chylothorax has been reported. Chest radiographic findings include a ground-glass appearance, prominent interstitial markings suggesting lymphatic distention, diffuse hyperlucency of the pulmonary parenchyma, and hyperinflation with depression of the diaphragm.

Congenital pulmonary lymphangiectasia may be associated with Noonan syndrome, asplenia, total anomalous pulmonary venous return, septal defects, atrioventricular canal, hypoplastic left heart, aortic arch malformations, and renal malformations. Patients with generalized lymphangieasia have less severe pulmonary disease.

**Prognosis**

The outcomes for children with congenital pulmonary lymphangiectasia are improving due to improvements in perinatal respiratory support and care. Most deaths occur within weeks after birth and thereafter respiratory symptoms improve after the first year of life suggesting that maximal medical treatment remains warranted. In those with the most severe disease, rapid diagnosis is essential in order to expedite the option of lung transplantation.

Scoliosis is defined as lateral curvature of the spine and is categorized as idiopathic, congenital, or neuromuscular. No pulmonary impairment is typically seen with a Cobb angle showing thoracic curvature of less than 35 degrees. Most cases of idiopathic scoliosis occur in adolescent girls and are corrected before significant pulmonary impairment occurs. Congenital scoliosis of severe degree or with other major abnormalities carries a more guarded prognosis. Patients with progressive neuromuscular disease, such as Duchenne muscular dystrophy, can be at risk for respiratory failure due to severe scoliosis and restrictive lung disease. Severe scoliosis can also lead to impaired lung function and, if uncorrected, possible death from cor pulmonale. (See also Chapter 26.) Small studies indicate that surgical correction of neuromuscular scoliosis should lead to improved quality of life, although pulmonary function may not improve.

**PECTUS CARINATUM**

Pectus carinatum is a protrusion of the upper or lower (more common) portion of the sternum, more commonly seen in males. Impairment of cardiopulmonary function due to pectus carinatum is debated. The decision to repair this deformity is often based upon cosmetic concerns. Patients with reduced endurance or dyspnea with mild exercise experienced marked improvement within 6 months following repair, suggesting possible physiologic indications. Pectus carinatum may be associated with systemic diseases such as the mucopolysaccharidoses and congenital heart disease.

**PECTUS EXCAVATUM**

Pectus excavatum is anterior depression of the chest wall that may be symmetrical or asymmetrical with respect to the midline. The effect of pectus excavatum on cardiopulmonary function is controversial. While subjective exertional dyspnea can be reported, and may improve with repair, objective cardiopulmonary function may not change postoperatively. Therefore, the decision to repair the deformity may be based on cosmetic or physiologic considerations.
Timing of repair is critical in light of growth plate maturation. Pectus excavatum may be associated with congenital heart disease, primary ciliary dyskinesia, and neuromuscular disorders.

NEUROMUSCULAR DISORDERS & LUNG DISEASE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Neuromuscular disease is associated with poor mucus clearance and restrictive lung disease in children.

Neuromuscular disorders are discussed in detail in Chapter 25. Weakness of the respiratory and pharyngeal muscles leads to chronic or recurrent pneumonia secondary to weak cough and poor mucus clearance, aspiration and infection, persistent atelectasis, hypoventilation, and respiratory failure in severe cases. Scoliosis, which frequently accompanies longstanding neuromuscular disorders, may further compromise respiratory function. Children born with significant neuromuscular weakness may present with signs and symptoms of respiratory compromise early in life. The time to presentation for children with progressive or acquired neuromuscular disease will depend upon the underlying neuromuscular defect. Typical examination findings in children at increased risk for pulmonary disease are a weak cough, decreased air exchange, crackles, wheezing, and dullness to percussion. The child also may have symptoms of hypoproteinemia or obstructive sleep apnea. Signs of cor pulmonale may be evident in advanced cases. Chest radiographs generally show small lung volumes. Other radiographic findings include abnormal rib orientation and generalized osteopenia of disuse. If chronic aspiration is present, increased interstitial infiltrates and areas of atelectasis or consolidation may be present. Arterial blood gases demonstrate hypoxemia in the early stages and compensated respiratory acidosis in the late stages. Typical pulmonary function abnormalities include decreased vital capacity, decreased inspiratory and/or expiratory pressure, and decreased peak cough flow.

Treatment is supportive and includes vigorous airway clearance with a focus on assisted cough maneuvers, noninvasive ventilation, and antibiotics with infection. Supple-

...
积累血液在胸膜腔内可能由手术或意外创伤，凝血缺陷，和胸膜或肺部肿瘤引起。胸水的定义为血液的血红蛋白含量超过50%的外周血液。胸腔内积血可能由创伤引起。症状与失血和压缩下肺组织相关。有二次感染的风险，导致脓胸。积血

**治疗**

胸腔内积血的治疗要求显著肺功能降低，如血胸。在没有复杂的情况下，观察是指示的，因为血液被吸收从胸膜腔内自发。VATS已经成功用于胸水管理。胸部CT扫描有助于选择需要手术的患者，识别血液和血液量可能比胸部射线片更预测通过这个方法从胸膜腔内。

**CHYLOTHORAX**

**主要诊断与典型表现**

- 呼吸困难与胸膜腔内积液的证据。
- 纤维素性胸膜炎显示含高脂肪消化产品的乳状液体（主要为脂质）。
- 积液在胸部影像学上通常由胸导管意外或外科创伤引起。新生儿胸水的常见原因是胸水。在较年长的儿童，胸水可以因为裂伤或阻塞的胸导管由于创伤或胸部手术（如心脏手术，脊柱成形术等）；阻塞的血管的良性或恶性肿块或淋巴结病；或增加静脉压力由于阻塞或左心室功能衰竭。症状与胸水积累和下肺组织的度压缩相关。胸腔穿刺显示典型的乳状液体（除非患者已经禁食）内以T-淋巴细胞为主。

**治疗**

治疗应该保守，因为许多胸水自发愈合。口服喂养中链脂肪酸减少乳液通过胸导管。生长抑素或长期生长抑素类似物，奥曲肽，是可行的治疗选择。胸腔内积液的治疗应该仅用于呼吸功能差，因为液体通常迅速重新积累。反复或持续的积液可能造成蛋白质营养不良和T-细胞的减少，使患者相对免疫功能降低。如果重新积液持续，手术胸导管结扎或硬化胸膜空间可以尝试，虽然结果可能不令人满意。

**PNEUMOTHORAX & RELATED AIR LEAK SYNDROMES**

**主要诊断与典型表现**

- 呼吸困难与胸膜腔内积液的证据。
- 胸腔积液从胸膜腔内积液
- 胸腔内积液可能由胸导管意外或外科创伤引起。新生儿胸水的常见原因是胸水。在较年长的儿童，胸水可以因为裂伤或阻塞的胸导管由于创伤或胸部手术（如心脏手术，脊柱成形术等）；阻塞的血管的良性或恶性肿块或淋巴结病；或增加静脉压力由于阻塞或左心室功能衰竭。症状与胸水积累和下肺组织的度压缩相关。胸腔穿刺显示典型的乳状液体（除非患者已经禁食）内以T-淋巴细胞为主。

**治疗**

治疗应该保守，因为许多胸水自发愈合。口服喂养中链脂肪酸减少乳液通过胸导管。生长抑素或长期生长抑素类似物，奥曲肽，是可行的治疗选择。胸腔内积液的治疗应该仅用于呼吸功能差，因为液体通常迅速重新积累。反复或持续的积液可能造成蛋白质营养不良和T-细胞的减少，使患者相对免疫功能降低。如果重新积液持续，手术胸导管结扎或硬化胸膜空间可以尝试，虽然结果可能不令人满意。
Pneumothorax can occur spontaneously in newborns and in older children, or more commonly, as a result of birth trauma, positive pressure ventilation, underlying obstructive or restrictive lung disease, or rupture of a congenital or acquired lung cyst. Pneumothorax can also occur as an acute complication of tracheostomy. Air usually dissects from the alveolar spaces into the interstitial spaces of the lung. Migration to the visceral pleura ultimately leads to rupture into the pleural space. Associated conditions include pneumomediastinum, pneumopericardium, pneumoperitoneum, and subcutaneous emphysema. These conditions are more commonly associated with dissection of air into the interstitial spaces of the lung with retrograde dissection along the bronchovascular bundles toward the hilum.

**Clinical Findings**

### A. Symptoms and Signs

The clinical spectrum can vary from asymptomatic to severe respiratory distress. Associated symptoms include cyanosis, chest pain, and dyspnea. Physical examination may reveal decreased breath sounds and hyperresonance to percussion on the affected side with tracheal deviation to the opposite side. When pneumothorax is under tension, cardiac function may be compromised, resulting in hypotension or narrowing of the pulse pressure. Pneumopericardium is a life-threatening condition that presents with muffled heart tones and shock. Pneumomediastinum rarely causes complications other than chest pain symptoms by itself.

### B. Laboratory Findings and Imaging Studies

Chest radiographs usually demonstrate the presence of free air in the pleural space. When the pneumothorax is large and under tension, compressive atelectasis of the underlying lung and shift of the mediastinum to the contralateral side may be observed. Cross-table lateral and lateral decubitus radiographs can aid in the diagnosis of free air. Pneumopericardium is identified by the presence of air completely surrounding the heart, whereas in patients with pneumomediastinum, the heart and mediastinal structures may be outlined with air, but the air does not involve the diaphragmatic cardiac border. Chest CT scan may be helpful with recurrent spontaneous pneumothoraces to look for subtle pulmonary disease not seen on chest radiograph, but this is debated.

### Differential Diagnosis

Acute deterioration of a patient on a ventilator can be caused by tension pneumothorax, obstruction or dislodgment of the endotracheal tube, or ventilator failure. Radiographically, pneumothorax must be distinguished from diaphragmatic hernia, lung cysts, congenital lobar emphysema, and cystic adenomatoid malformation, but this task is usually not difficult.

**Treatment**

Small (<15%) or asymptomatic pneumothoraces usually do not require treatment and can be managed with close observation. Larger or symptomatic pneumothoraces require drainage, although inhalation of 100% oxygen to wash out blood nitrogen can be tried. Needle aspiration should be used to relieve tension acutely, followed by chest tube or pigtail catheter placement. Pneumopericardium requires immediate identification, and if clinically symptomatic, needle aspiration to prevent death, followed by pericardial tube placement.

### Prognosis

In older patients with spontaneous pneumothorax, recurrences are common; sclerosing and surgical procedures are often required.

---

**MEDIASTINUM**

### MEDIASTINAL MASSES

#### ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- **Presentation varies depending on the location of the mass.**
- **Most mediastinal masses are discovered on routine chest x-rays.**

Children with mediastinal masses may present because of symptoms produced by pressure on the esophagus, airways, nerves, or vessels within the mediastinum, or the masses may be discovered on a routine chest radiograph. Once the mass is identified, localization to one of four mediastinal compartments aids in the differential diagnosis. The superior mediastinum is the area above the pericardium that is bordered inferiory by an imaginary line from the manubrium to the fourth thoracic vertebra. The anterior mediastinum is bordered by the sternum anteriorly and the pericardium posteriorly, and the posterior mediastinum is defined by the pericardium and diaphragm anteriorly and the lower eight thoracic vertebrae posteriorly. The middle mediastinum is surrounded by these three compartments.
Clinical Findings

A. Symptoms and Signs

Respiratory symptoms, when present, are due to pressure on an airway (cough or wheezing) or an infection (unresolving pneumonia in one area of lung). Hemoptysis can also occur but is an unusual presenting symptom. Dysphagia may occur secondary to compression of the esophagus. Pressure on the recurrent laryngeal nerve can cause hoarseness due to paralysis of the left vocal cord. Superior vena caval syndrome presents with dilation of neck vessels and other signs and symptoms of venous obstruction; superior mediastinal syndrome presents similarly but includes tracheal compression.

B. Laboratory Findings and Imaging Studies

The mass is initially defined by frontal and lateral chest radiographs together with thoracic CT scans or MRI. A barium esophagram may help define the extent of a mass. Other studies that may be required include angiography (to define the blood supply to large tumors), electrocardiography, echocardiography, ultrasound of the thorax, fungal and mycobacterial skin tests, and urinary catecholamine assays. MRI or myelography may be necessary in children suspected of having a neurogenic tumor in the posterior mediastinum. Mediastinal masses, particularly anterior masses, can cause life-threatening airway compromise during sedation even in patients with mild symptoms; thus, any sedation or anesthesia should be avoided if possible and performed cautiously.

Differential Diagnosis

The differential diagnosis of mediastinal masses is determined by their location. Within the superior mediastinum, one may find cystic hygromas, vascular or neurogenic tumors, thymic masses, teratomas, intrathoracic thyroid tissue, mediastinal abscess, and esophageal lesions. Within the anterior mediastinum, thymic tissue (thymomas, hyperplasia, cysts and intrathoracic thyroid) and teratomas, vascular tumors, and lymphatic tissue give rise to masses (lymphomas, leukemia, or reactive lymphadenopathy). Within the middle mediastinum masses include lymphomas and hyper trophy lymph nodes, granulomas, bronchogenic or enterogenous cysts, metastases, and pericardial cysts. Abnormalities of the great vessels and aortic aneurysms may also present as masses in this compartment. Within the posterior mediastinum, neurogenic tumors, enterogenous cysts, thoracic meningoceles, or aortic aneurysms may be present.

In some series, more than 50% of mediastinal tumors occur in the posterior mediastinum and are mainly neurogenic tumors or enterogenous cysts. Most neurogenic tumors in children younger than 4 years are malignant (neuroblastoma or neuroganglioblastoma), whereas a benign ganglieneuroma is the most common histologic type in older children. In the middle and anterior mediastinum, lymphoma and leukemia are the primary concern. Definitive diagnosis in most instances relies on surgical removal or biopsy for histologic examination.

Treatment & Prognosis

The appropriate therapy and the response to therapy depend on the cause of the mediastinal mass.

Sleep-Disordered Breathing

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Nighttime symptoms of snoring, apnea, or obstruction.
- Sleep studies are used to diagnose sleep apnea and to guide treatment.

Sleep apnea is recognized as a major public health problem in adults, due to its associated impact on health and the risks of excessive daytime sleepiness, impairment while driving, poor work performance, and effects on health. Pediatric sleep disorders are less commonly recognized because the risk factors, presentations, management, and outcomes differ from those in adults although the adverse impact on health is similar in scope and severity. The spectrum of sleep-disordered breathing includes obstructive sleep apnea, periodic breathing, central sleep apnea, and primary snoring. Snoring, mouth breathing, and upper airway obstruction are discussed in Chapter 18.

Obstructive & Central Sleep Apnea

Clinical Findings and Differential Diagnosis

Sleep apnea is defined as cessation of breathing and can be classified as obstructive (the attempt to breathe through an obstructed airway) or central (the lack of effort to breathe). Obstructive sleep apnea (OSA) occurs in normal children with an incidence of about 2%, increasing in children with medical conditions, such as craniofacial abnormalities or neuromuscular diseases. The incidence also increases when children are medicated with hypnotics, sedatives, or anticonvulsants. While not all children with habitual snoring (snoring 3 or more nights per week) have sleep apnea,
there is evidence that that even primary snoring (habitual snoring without gas exchange abnormalities) has neurobehavioral consequences. Obstructive sleep apnea should be suspected whenever a child presents with symptoms of loud habitual snoring, witnessed apnea, labored breathing, or frequent nighttime arousals, especially in the setting of failure to thrive or obesity, nocturnal oxygen desaturations, life-threatening events, craniofacial abnormalities, poor school performance, or behavioral problems such as hyperactivity. In children, airway obstruction is often associated with adenotonsillar hypertrophy or nasal congestion. Tonsillar hypertrophy is most common between the ages of 2 and 7 years. Obesity is widely recognized as an etiologic component in adult OSA and is similarly cited in children. Consequences of OSA include failure to thrive, pulmonary hypertension, deficits of cognition, poor school performance, and psychiatric or behavioral problems. Central apneas are seen in infants and children, particularly at increased elevation. These are pauses in breathing without concomitant effort and may occur in a pattern of alternating apnea and tachypnea known as periodic breathing. Clinical significance is uncertain, as healthy children have been shown to have central apneas lasting 25 seconds without clear consequences. These central respiratory events may be relevant if they occur frequently or are associated with gas exchange abnormalities or sleep fragmentation, and should prompt a thorough evaluation.

**Diagnostic Studies**

Clinical history and physical examination alone are inadequate to distinguish periodic breathing and primary snoring from central sleep apnea and obstructive sleep apnea in children, therefore polysomnography should be performed in all suspected cases. This test measures sleep state with electroencephalogram leads and electromyography, airflow at the nose, chest and abdominal muscle movement, heart rate and rhythm, gas exchange (CO₂ and O₂), and leg movements, along with other data including body position, vibrations representing snoring, and audiovisual recording. Polysomnography allows diagnosis of both central and central apnea, sleep fragmentation, periodic limb movement disorder, or other sleep disorders of children. Overnight oximetry and home polysomnography (typically limited to 4 or fewer parameters) are not ideal studies to evaluate pediatric sleep disorders. While these tests may identify subjects with severe obstructive sleep apnea, the sensitivity is low. For example, normal oximetry studies are obtained in half of subjects with polysomnographically confirmed obstructive sleep apnea.

**Treatment**

First-line therapy for obstructive sleep apnea in children is adenotonsillectomy, which improves the clinical status for most nonobese children with normal craniofacial structure. Even children with obesity, craniofacial anomalies or neuromuscular disorders may benefit, although additional treatment with continuous positive airway pressure (CPAP) may be indicated. Regardless of underlying etiologies, maintaining a healthy weight, addressing abnormal dentition (with the use of orthodontics, including oral appliances and maxillary expanders if necessary) and optimizing airway health (by treating nasal obstruction and asthma with topical intranasal steroids and leukotriene modifiers, for example) are cornerstones of OSA and primary snoring management. Down syndrome presents unique challenges: up to half of these children can still have OSA despite adenotonsillectomy. Treatment of young or developmentally delayed children with apnea is challenging due to ongoing growth and development, barriers to adherence, difficulties of long-term therapies. (See Chapter 18 for additional discussion.) Though no intervention is needed in most cases of periodic breathing and central sleep apnea, supplemental oxygen may be needed to reduce oxygen desaturation and stabilize the respiratory pattern.

The presentation of sleep apnea is quite varied among children. Therefore, referral to a pediatric sleep disorder centers should be considered.

**APPARENT LIFE-THREATENING EVENTS**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Acute, unexpected change in breathing that leads the frightened observer to fear that the infant has died.
- Thoracocentesis reveals blood in the pleural space.

Apparent life-threatening events (ALTEs) are defined by an acute, unexpected change in an infant’s breathing, appearance, or behavior that is frightening to the observer, who may fear that the infant has died or almost died. ATLEs are characterized by some combination of apnea, color change (usually cyanosis or pallor), a marked change in muscle tone (usually limpness), choking, or gagging. The relationship between ALTE and future risk of sudden infant death...
syndrome (SIDS) or sudden unexpected infant death (SUID) is not clear, as ALTE infants tend to be slightly younger. The term apparent life-threatening event replaced “near-miss SIDS” in order to distinguish the event from a direct association with SIDS. The risk of SIDS or SUID is higher when extreme cardiopulmonary events were required at the time of the ALTE. About 12%–15% of both SIDS victims and infants dying unexpectedly of a known cause have had a prior history of ALTE, but most do not.

ALTE is not a specific diagnosis; up to 50% of ALTEs remain unexplained and are referred to as apnea of infancy. The most frequent problems identified with an ALTE are gastrointestinal (~50%), neurologic (30%), respiratory (20%), cardiovascular (5%), and metabolic or endocrine (< 5%), but can be caused by myriad other problems, including nonaccidental trauma. Because ALTEs do not occur after infancy, immaturity likely plays a major role. Classic studies on the nervous system, reflexes, or responses to apnea or gastroesophageal reflux during sleep in infants and immature animals show profound cardiovascular changes during stimulation of the vagus nerve, whereas adults would not be affected. The following section describes an approach to the patient who has experienced an ALTE, taking note of the very broad differential diagnosis and uncertainties in both evaluation and treatment.

Clinical Findings and Differential Diagnosis

A. Symptoms and Signs

Table 19–7 classifies disorders associated with ALTEs. The causes of ALTEs are diverse and multifactorial, but it is the response to the trigger that creates a symptom cluster unique to infants. A careful history is the most helpful part of the evaluation. In a large epidemiological study of infants who died of SIDS or SUID, a careful history using a “baby check” score was useful in identifying infants who were seriously ill. It is useful to determine whether the infant has been ill or essentially well. A history of several days of poor feeding, temperature instability, or respiratory or gastrointestinal symptoms suggests an infectious process. Reports of “struggling to breathe” or “trying to breathe” imply airway obstruction. Episodes following crying may be related to breath-holding. Association of the episode with feeding implies discoordinated swallowing with or without aspiration, gastroesophageal reflux, or delayed gastric emptying, or may imply an airway abnormality. Episodes occurring while awake are associated with very different diagnoses than episodes occurring during sleep. Association of episodes with sleep may also suggest seizure, gastroesophageal reflux, apnea of infancy, or sleep-disordered breathing. Attempts should be made to determine the duration of the episode, but this is often difficult. It is helpful to role-play the episode with the family. Details regarding the measures taken to resuscitate the infant and the infant’s recovery from the episode may be useful in determining severity.

The physical examination provides further direction in pursuing the diagnosis. Fever or hypothermia suggests infection. An altered state of consciousness implies a postictal state or drug overdose, or central nervous system anomaly or infection. Respiratory distress implies cardiac or pulmonary lesions. Apneic episodes have been linked to child abuse in several ways. Head injury following nonaccidental trauma may be first brought to medical attention because of apnea. Other signs of abuse are usually immediately apparent in such cases. Drug overdose, either accidental or intentional, may also present with apnea. Several studies document that apneic episodes may be falsely reported by parents who are seeking attention (ie, Munchausen syndrome by proxy). Parents may physically interfere with a child’s respiratory efforts, in which case pinch marks on the nares are sometimes found.

B. Laboratory Findings

Most patients are hospitalized for observation in order to reduce stress on the family and allow prompt completion

| Table 19–7. Potential causes of apparent life-threatening events. |
|---|---|
| **Infectious** | Viral: respiratory syncytial virus and other respiratory viruses |
| | Bacterial: sepsis, pertussis, Chlamydia |
| **Gastrointestinal** | Gastroesophageal reflux with or without obstructive apnea |
| **Respiratory** | Airway abnormality; vascular rings, pulmonary slings, tracheomalacia |
| | Pneumonia |
| **Neurologic** | Seizure disorder |
| | Central nervous system infection: meningitis, encephalitis |
| | Vasovagal response |
| | Leigh encephalopathy |
| | Brain tumor |
| **Cardiovascular** | Congenital malformation |
| | Dysrhythmias |
| | Cardiomyopathy |
| **Nonaccidental trauma** | Battering |
| | Drug overdose |
| | Munchausen syndrome by proxy |
| **No definable cause** | Apnea of infancy |
of the evaluation. Diagnostic testing should be based very heavily on the history and physical examination. Laboratory evaluation might include a complete blood count, blood culture with urinalysis and urine culture for evidence of infection, especially in the face of fever, hypothermia, or an abnormal physical examination. Serum electrolytes may reveal electrolyte disturbances from metabolic disorders, dehydration, or ingestions. An elevation in serum bicarbonate suggests chronic hyperventilation, whereas decreases suggest acute acidosis, perhaps due to hypoxia during the episode. Chronic acidosis suggests an inherited metabolic disorder. Arterial blood gas studies provide an initial assessment of oxygenation and acid-base status. Low Pao₂ or elevated Paco₂ (or both) implies cardiopulmonary disease. A significant base deficit suggests that the episode was accompanied by hypoxia or circulatory impairment. Oxygen saturation measurements in the hospital assess oxygenation status during different activities and are more comprehensive than a single blood gas sample. Because apnea has been associated with respiratory infections, diagnostic studies for RSV and other viruses, pertussis, and Chlamydia may help with diagnosis. Apnea occurring with infection often precedes other physical findings.

C. Imaging Studies

The chest radiograph is examined for infiltrates suggesting acute infection or chronic aspiration and for cardiac size as a clue to intrinsic cardiac disease. Electrocardiogram is helpful to rule out cardiac dysrhythmias, and echocardiogram may be indicated if there is suspicion of congenital heart disease based on history and physical examination. If the episode might have involved airway obstruction, the airway should be examined either directly by fiberoptic bronchoscopy or radiographically by CT or barium swallow. Barium swallow is a useful tool to rule out the possibility of anatomic abnormalities such as vascular ring and tracheoesophageal fistula. Gastroesophageal reflux is one of the most common findings in infants with ALTE; however, it may be a marker of autonomic immaturity as opposed to a diagnosis for the event. Most infants with reflux and apnea can be given medical antireflux treatment. Infants with reflux and repeated episodes of apnea may benefit from a surgical antireflux procedure.

D. Special Tests: Polysomnography and Other Studies

ALTEs occur in the same age group as infants who die of SUID (2–4 months is the peak age). Sleep-disordered breathing has been implicated as a possible cause of ALTEs and perhaps sudden death. Depending on the discretion of the clinician polysomnography can be useful in detecting abnormalities of cardiorespiratory function, sleep state, oxygen saturation, carbon dioxide retention, and seizure activity. Sleep studies can be used in conjunction with pH monitoring to determine the contribution of reflux to apnea. Esophageal pressure manometry can be useful to detect subtle changes in respiratory effort related to partial obstructive breathing (hypopnea). Due to their immature nervous system, infants are more likely to experience adverse events from sleep-disordered breathing than adults.

Among the neurologic causes of ALTEs, seizure disorder has been found to be a cause of ALTE in a significant number of cases. Apnea as the sole manifestation of a seizure disorder is unusual but may occur. In cases of repeated episodes, 24-hour electroencephalographic monitoring may be helpful in detecting a seizure disorder.

▶ Treatment

Therapy is directed at the underlying cause if one is found. After blood cultures are taken, antibiotics should be given to infants who appear toxic. Seizure disorders are treated with anticonvulsants. Gastroesophageal reflux should be treated, but may not prevent future episodes of ALTE. Vascular rings and pulmonary slings must be corrected surgically because of severe morbidity and high mortality rates when untreated.

The approach to care of infants with ALTEs where no cause can be ascertained is controversial. Home monitoring has been used in the past as treatment, but the efficacy of monitoring has not been demonstrated in controlled trials. After more than 30 years of home monitoring, the sudden infant death rate has not changed. Although monitors can detect central apnea or bradycardia, they do not predict which children will have future ALTEs or SUID, and they do not detect obstructive forms of breathing, which is a common form of apnea in infants. Apnea monitors are prone to frequent false alarms, and it must be noted that many parents cannot handle the stress associated with having a monitor in the home. Parents should be taught cardiopulmonary resuscitation prior to discharge and should prevent modifiable risk factors for infant death discussed below. Infants with severe initial episodes or repeated severe episodes should be considered at significantly increased risk for SUID. A monitor with an oxygen saturation detection capability may identify episodes earlier. The caregiver responsible for prescribing a monitor should have a plan for data acquisition and future discontinuation of the monitor so that the parents can be prepared.

Supplemental oxygen has been used as therapy for ALTEs for several reasons. Oxygen reduces periodic breathing of infancy, an immature pattern of breathing that can cause some degree of oxygen desaturation. Second, infants have small chest capacities with increased chest wall compliance that reduces lung volume. Supplemental oxygen can increase the baseline saturation, reducing the severity of desaturation with short apneas. Respiratory stimulants such
as caffeine and aminophylline have been used in specific cases of central apnea or periodic breathing.

All infants younger than 1 year should be evaluated for the presence of modifiable SUID risk factors. Parents should be educated on how to avoid these risk factors, especially in infants at increased risk such as former preterm infants, children exposed to cigarette smoke environmentally or prior to birth, African American or Native American infants, and infants in poor socioeconomic areas. Updates on recommendations for the prevention of unexpected death in infants were published by the American Academy of Pediatrics in 2016. New recommendations include:

- Infants should sleep in the parents’ room, close to the parents’ bed but on a separate surface designed for infants, ideally for the first year of life but at least for the first 6 months.
- Soft objects and loose bedding, including blankets and nonfitted sheets, should be kept away from the infant’s sleep area to reduce the risk of SIDS, suffocation, entrapment, and strangulation. Wearable blankets are preferred to blankets and other coverings to keep the infant warm while reducing the chance of head covering.
- There is no evidence to recommend swaddling as a strategy to reduce the risk of SIDS.
- There are no studies supporting the safety of bedside or in-bed sleepers, and therefore these products cannot be recommended.
- Health care professionals, hospital staff, and child care providers should endorse and model infant safe sleep recommendations from birth.
- Pediatricians and other primary care providers should actively participate in the “Safe to Sleep” campaign, focusing on ways to reduce the risk of all sleep-related infant deaths, including SIDS, suffocation, and other unintentional deaths.

In addition, the updated guidelines reiterated the importance of other long-standing recommendations, including:

- Always place a baby on its back to sleep (this includes a baby with reflux).
- There should be nothing in a baby’s sleep space other than the baby, such as blankets, pillows, stuffed animals, or wedge positioners.
- Avoid overheating, overwrapping, and covering the face and head. Breast-feeding is recommended.
- Consider offering a pacifier at naptime and bedtime.
- Avoid exposure to cigarette smoke during pregnancy and after birth.
- Car seats, swings, and baby slings should not be used for sleep as the infant’s head tends to fall forward or to the side, compromising the airway.

- Avoid the use of adult beds, bed rails, and in-bed co-sleepers, which increase the risk of suffocation and entrapment.

### SUDDEN UNEXPECTED INFANT DEATH & SUDDEN INFANT DEATH SYNDROME

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

SIDS is defined as the sudden death of an infant younger than 1 year that remains unexplained after a thorough case investigation, including performance of a complete autopsy, examination of the death scene, and review of the clinical history. The postmortem examination is an important feature of the definition because approximately 20% of cases of sudden death can be explained by autopsy findings. After the “Back to Sleep” campaign began in the United States in 1994, the incidence of SIDS declined from approximately 2 per 1000 to 0.5 per 1000 live births. However, the incidence of SIDS has leveled off since 1999.

SUID, defined as any sudden and unexpected infant death, whether explained (such as accidental suffocation or strangulation) or unexplained (such as SIDS) has gained favor as the preferred term to refer to infant deaths that were previously classified as SIDS. SIDS is neither a true diagnosis nor a syndrome, and labeling an infant death as SIDS tends to give parents a false sense that the cause of their child’s death is known and understood. SUID also includes deaths due to infection, ingestions, metabolic diseases, cardiac arrhythmias, and trauma. New evidence shows that the incidence of accidental suffocation and strangulation in bed is increasing due to unsafe sleep surfaces and environments.

**Epidemiology and Pathogenesis**

Epidemiologic and pathologic data constitute most of what is known about SUID. Like SIDS, SUID deaths peak between ages 2 and 4 months. Most deaths occur at night, while the infant and the caregiver are sleeping. In fact, the only unifying features of all cases are age and sleep. SUID is more common among ethnic and racial minorities and socioeconomically disadvantaged populations. Racial disparity in the prevalence of prone positioning and especially in bed-sharing may be contributing to the continued disparity in SUID rates between black and white infants. There is a 3:2 male predominance in most series. Other risk factors...
include premature birth, low birth weight, recent infection, young maternal age, high maternal parity, maternal tobacco or drug use, and crowded living conditions. Most of these risk factors are associated with a two- to three-fold increased incidence but are not specific enough to be useful in predicting which infants will die unexpectedly. Recent immunization is not a risk factor.

The most consistent pathologic findings in SUID deaths from unknown cause (previously classified as SIDS) are intrathoracic petechiae and mild inflammation and congestion of the respiratory tract. More subtle pathologic findings include brainstem gliosis, extramedullary hematopoiesis, and increases in peri-adrenal brown fat. These latter findings suggest that infants who succumb to SUID have had intermittent or chronic hypoxia before death.

In cases where a distinct cause cannot be identified, the mechanism or mechanisms of death in SUID are unknown. For example, it is unknown whether the initiating event at the time of death is cessation of breathing, cardiac arrhythmia, or asystole. Hypotheses have included upper airway obstruction, catecholamine excess, and increased fetal hemoglobin. However, maldevelopment or delayed maturation of the brainstem, which is responsible for arousal from sleep, remains the predominant theory. A history of mild symptoms of upper respiratory infection before death is not uncommon, and SUID victims are sometimes seen by physicians a day or so before death. The postmortem examination is essential and may help the family by excluding other possible causes of death. A death scene investigation is also important in determining the cause of sudden unexpected deaths in infancy.

Families must be supported following the death of an infant. The National SIDS Resource Center (http://www.sidscenter.org) provides information about psychosocial support groups and counseling for families of SIDS victims.

**Prevention**

Since 1990, SIDS rates have declined more than 60% worldwide. Population studies in New Zealand and Europe identified risk factors, which when changed had a significant effect on the incidence of SIDS. Since 1994 the American Academy of Pediatrics’ “Back-to-Sleep” campaign has promoted education about the risk of prone positioning. The new updated recommendations can be found in AAP Task Force report referenced below. Modifiable risk factors include sleep position, location, and environment; formula feeding; maternal smoking or drug use; and infant overheating. The prone sleep position may increase the risk of SUID through decreased arousal or rebreathing of exhaled gases. Side positioning, often used in hospitals and then mimicked at home, increases risk of SUID compared with the supine position and is not a safe alternative to supine sleep, even in infants with reflux. Environmental smoke exposure, especially prenatal maternal smoking, increases the risk of SUID. SUID risk is decreased when an infant is breastfed and when a pacifier is offered at naptime and bedtime.

The healthcare provider is instrumental in parental education regarding the modifiable risk factors for SUID. Education and appropriate modeling of safe sleep behaviors should begin in the hospital immediately after birth. The healthcare provider should screen all infants for SUID risk factors and be mindful of the childcare setting, where risk factors may not be recognized or addressed. Hospitals should set an example by placing infants in the supine position with no blankets, pillows, or other soft objects in the bed prior to discharge. At present, the data show that the environment is key to the safety of the infant, and unsafe sleep environments are responsible for the recent increase in accidental suffocation, asphyxia, and entrapment.

**QUALITY ASSESSMENT & OUTCOMES METRICS**

Pediatric pulmonary medicine is constantly adjusting to improve the outcomes for children with respiratory illness. The foundation of the work in quality improvement is in the many Clinical Care Guidelines that inform the care of patients and in the data that indicate the success of the care. For example, as mentioned (and referenced) earlier the Cystic Fibrosis (CF) Foundation works with providers and centers of care to create and implement guidelines for the diagnosis and management of children with CF. The CF foundation also maintains a registry of children with CF and reports on outcomes including lung function, body mass index, and mortality data. The ChILD foundation mentioned earlier has also created guidelines for diagnosis and management and follows patient outcomes including those mentioned above. The National Heart, Lung, and Blood Institute has updated the asthma guidelines three times. International
and United States based organizations have studied adherence to those guidelines. The Center for Disease Control in the United States reports asthma outcomes including utilization, mortality, and cost of care. The American Academy of Pediatrics, as mentioned earlier, has published guidelines for SIDS and SUID prevention. There are ongoing studies of the impact of those guidelines and the data demonstrates clearly that these guidelines are saving lives. Finally, respiratory disease requires a multidisciplinary team to care for patients in and out of the hospital. The American Academy of Respiratory Care publishes guidelines on oxygen use, aerosolized device use, and ventilation (acute and chronic) for pediatric patients.
INTRODUCTION

Eight in 1000 infants are born with a congenital heart defect. Advances in medical and surgical care allow more than 90% of such children to enter adulthood. Pediatric cardiac care includes not only the diagnosis and treatment of congenital heart disease but also the prevention of risk factors for adult cardiovascular disease—obesity, smoking, and hyperlipidemia. Acquired and familial heart diseases such as Kawasaki disease, viral myocarditis, cardiomyopathies, and rheumatic heart disease are also a significant cause of morbidity and mortality in children.

DIAGNOSTIC EVALUATION

HISTORY

Symptoms related to congenital heart defects primarily vary according to the alteration in pulmonary blood flow (Table 20–1). The presence of other cardiovascular symptoms such as palpitations and chest pain should be determined by history in the older child, paying particular attention to the timing (at rest or activity-related), onset, and termination (gradual vs sudden), as well as precipitating and relieving factors.

PHYSICAL EXAMINATION

General

The examination begins with a visual assessment of mental status, signs of distress, perfusion, and skin color. Documentation of heart rate, respiratory rate, blood pressure (in all four extremities), and oxygen saturation is essential. Many congenital cardiac defects occur as part of a genetic syndrome (Table 20–2), and complete assessment includes evaluation of dysmorphic features that may be clues to the associated cardiac defect.

Cardiovascular Diseases

Pei-Ni Jone, MD  Jeffrey R. Darst, MD
Johannes VonAlvensleben, MD  Kathryn K. Collins, MD
Dale Burkett, MD  Shelley D. Miyamoto, MD

Cardiovascular Examination

A. Inspection and Palpation

Chest conformation should be noted in the supine position. A precordial bulge indicates cardiomegaly. Palpation may reveal increased precordial activity, right ventricular lift, or left-sided heave; a diffuse point of maximal impulse; or a precordial thrill caused by a grade IV/VI or greater murmur. The thrill of aortic stenosis is found in the suprasternal notch. In patients with severe pulmonary hypertension, a palpable pulmonary closure (P₂) is frequently noted at the upper left sternal border.

B. Auscultation

1. Heart sounds—The first heart sound (S₁) is the sound of atrioventricular (AV) valve closure. It is best heard at the lower left sternal border and is usually medium pitched. Although S₁ has multiple components, only one of these (M₁ —closure of the mitral valve) is usually audible. The second heart sound (S₂) is the sound of semilunar valve closure. It is best heard at the upper left sternal border. S₂ has two component sounds, A₂ and P₂ (aortic and pulmonary valve closure). Splitting of S₂ varies with respiration, widening with inspiration and narrowing with expiration. Abnormal splitting of S₂ may be an indication of cardiac disease (Table 20–3). A prominent or loud P₂ is associated with pulmonary hypertension.

   The third heart sound (S₃) is the sound of rapid left ventricular filling. It occurs in early diastole, after S₂, and is medium- to low-pitched. In healthy children, S₃ diminishes or disappears when going from supine to sitting or standing. A pathologic S₃ is often heard in the presence of poor cardiac function or a large left-to-right shunt. The fourth heart sound (S₄) is associated with atrial contraction and increased atrial pressure and has a low pitch similar to that of S₃. It occurs just prior to S₁ and is not normally audible. It is heard...
CHAPTER 20

in the presence of atrial contraction into a noncompliant ventricle as in hypertrophic or restrictive cardiomyopathy or from other causes of diastolic dysfunction.

Ejection clicks are usually related to dilate great vessels or valve abnormalities. They are heard during ventricular systole and are classified as early, mid, or late. Early ejection clicks at the mid-left sternal border are from the pulmonic valve. Aortic clicks are typically best heard at the apex. In contrast to aortic clicks, pulmonic clicks vary with respiration, becoming louder during inspiration. A mid to late ejection click at the apex is most typically caused by mitral valve prolapse.

2. Murmurs—A heart murmur is the most common cardiovascular finding leading to a cardiology referral. Innocent or functional heart murmurs are common, and 40%–45% of children have an innocent murmur at some time during childhood.

a. Characteristics—All murmurs should be described based on the following characteristics:

(1) Location and radiation—Where the murmur is best heard and where the sound extends.

(2) Relationship to cardiac cycle and duration—Systolic ejection (immediately following S1 with a crescendo/decrescendo change in intensity), pansystolic (occurring throughout most of systole and of constant intensity), diastolic, or continuous. The timing of the murmur provides valuable clues as to the underlying pathology (Table 20–4).

(3) Intensity—Grade I describes a soft murmur heard with difficulty; grade II, soft but easily heard; grade III, loud but without a thrill; grade IV, loud and associated with a precordial thrill; grade V, loud, with a thrill, and audible with the edge of the stethoscope; grade VI, very loud and audible with the stethoscope off the chest.

(4) Quality—Harsh, musical, or rough; high, medium, or low in pitch.

(5) Variation with position—Audible changes in murmur when the patient is supine, sitting, standing, or squatting.

b. Innocent murmurs—The six most common innocent murmurs of childhood are as follows:

(1) Newborn murmur—Heard in the first few days of life, this murmur is at the lower left sternal border, without significant radiation. It has a soft, short, vibratory grade I–II/VI quality that often subsides when mild pressure is applied to the abdomen. It usually disappears by age 2–3 weeks.

(2) Peripheral pulmonary artery stenosis (PPS)—This murmur, often heard in newborns, is caused by the normal branching of the pulmonary artery. It is heard with equal intensity at the upper left sternal border, at the back, and in one or both axillae. It is a soft, short, high-pitched, grade I–II/VI systolic ejection murmur and usually disappears by age 2. This murmur must be differentiated from true peripheral pulmonary stenosis (Williams syndrome, Alagille

syndrome, or rubella syndrome), coarctation of the aorta, and valvular pulmonary stenosis. Characteristic facial features, extracardiac physical examination findings, history, and laboratory abnormalities suggestive of the syndromes listed above are the best way to differentiate true peripheral pulmonary stenosis from benign PPS of infancy as the murmurs can be similar.

(3) Still murmur—This is the most common innocent murmur of early childhood. It is typically heard between 2 and 7 years of age. It is the loudest midway between the apex and the lower left sternal border. Still murmur is a musical or vibratory, short, high-pitched, grade I–III early systolic murmur. It is loudest when the patient is supine. It diminishes or disappears with inspiration or when the patient is sitting. The still murmur is louder in patients with fever, anemia, or sinus tachycardia from any reason.

(4) Pulmonary ejection murmur—This is the most common innocent murmur in older children and adults. It is heard from age 3 years onward. It is usually a soft systolic ejection murmur, grade I–II in intensity at the upper left sternal border. The murmur is louder when the patient is supine or when cardiac output is increased.

(5) Venous hum—A venous hum is usually heard after age 2 years. It is located in the infraclavicular area on the right. It is a continuous musical hum of grade I–III intensity and may be accentuated in diastole and with inspiration. It is best heard in the sitting position. Turning the child’s neck, placing the child supine, and compressing the jugular vein obliterates the venous hum. Venous hum is caused by turbulence at the confluence of the subclavian and jugular veins.

(6) Innominate or carotid bruit—This murmur is more common in the older child and adolescents. It is heard in the right supraclavicular area. It is a long systolic ejection murmur, somewhat harsh and of grade II–III intensity. The bruit can be accentuated by light pressure on the carotid artery and must be differentiated from all types of aortic stenosis. The characteristic findings of aortic stenosis are outlined in more detail later in this chapter.

When innocent murmurs are found in a child, the physician should assure the parents that these are normal heart sounds of the developing child and that they do not represent heart disease.

Extracardiac Examination

A. Arterial Pulse Rate and Rhythm

Cardiac rate and rhythm vary greatly during infancy and childhood, so multiple determinations should be made. This is particularly important for infants (Table 20–5) whose heart rates vary with activity. The rhythm may be regular or there may be a normal phasic variation with respiration (sinus arrhythmia).

B. Arterial Pulse Quality and Amplitude

A bounding pulse is characteristic of run-off lesions, including patent ductus arteriosus (PDA), aortic regurgitation, arteriovenous malformation, or any condition with a low diastolic pressure (fever, anemia, or septic shock). Narrow or thready pulses occur in patients with conditions reducing cardiac output such as decompensated heart failure pericardial tamponade, or severe aortic stenosis. A reduction in pulse amplitude or blood pressure (> 10 mm Hg) with inspiration is referred to as pulsus paradoxus and is a sign of pericardial tamponade. The pulses of the upper and lower extremities should be compared. The femoral pulse should be palpable and equal in amplitude and simultaneous with the brachial pulse. A femoral pulse that is absent or weak, or

that is delayed in comparison with the brachial pulse, suggests coarctation of the aorta.

**C. Arterial Blood Pressure**

Blood pressures should be obtained in the upper and lower extremities. Systolic pressure in the lower extremities should be greater than or equal to that in the upper extremities. The cuff must cover the same relative area of the arm and leg. Measurements should be repeated several times. A lower blood pressure in the lower extremities suggests coarctation of the aorta.

**D. Cyanosis of the Extremities**

Cyanosis results from an increased concentration (> 4–5 g/dL) of reduced hemoglobin in the blood. Bluish skin color is usually, but not always, a sign. Visible cyanosis also accompanies low cardiac output, hypothermia, and systemic venous congestion, even in the presence of adequate oxygenation. Cyanosis should be judged by the color of the mucous membranes (lips). Bluish discoloration around the mouth (acrocyanosis) does not correlate with cyanosis.

**E. Clubbing of the Fingers and Toes**

Clubbing is often associated with severe cyanotic congenital heart disease. It usually appears after age 1 year. Hypoxemia with cyanosis is the most common cause, but clubbing also occurs in patients with endocarditis, chronic liver disease, inflammatory bowel diseases, chronic pulmonary disease, and lung abscess. Digital clubbing may be a benign genetic variant.

**F. Edema**

Edema of dependent areas (lower extremities in the older child and the face and sacrum in the younger child) is characteristic of elevated right heart pressure, which may be seen with tricuspid valve pathology or heart failure.

**G. Abdomen**

Hepatomegaly is the cardinal sign of right heart failure in the infant and child. Left heart failure can ultimately lead to right heart failure and therefore, hepatomegaly may also be seen in the child with pulmonary edema from lesions causing left-to-right shunting (pulmonary overcirculation) or left ventricular failure. Splenomegaly may be present in patients with long-standing heart failure (HF), and is also a characteristic of infective endocarditis. Ascites is a feature of chronic right heart failure. Examination of the abdomen may reveal shifting dullness or a fluid wave.

---

**ELECTROCARDIOGRAPHY**

The electrocardiogram (ECG) is essential in the evaluation of the cardiovascular system. The heart rate should first be determined, then the cardiac rhythm (Is the patient in a normal sinus rhythm or other rhythm as evidenced by a P wave with a consistent PR interval before every QRS complex?), and then the axis (Are the P and QRS axes normal for patient age?). Finally, assessment of chamber enlargement, cardiac intervals, and ST segments should be performed.

**Age-Related Variations**

The ECG evolves with age. The heart rate decreases and intervals increase with age. RV dominance in the newborn changes to LV dominance in the older infant, child, and adult. The normal ECG of the 1-week-old infant is abnormal for a 1-year-old child, and the ECG of a 5-year-old child is abnormal for an adult.

**Electrocardiographic Interpretation**

Figure 20–1 defines the events recorded by the ECG.

**A. Rate**

The heart rate varies markedly with age, activity, and state of emotional and physical well-being (see Table 20–5).

**B. Rhythm**

Sinus rhythm should always be present in healthy children. Extra heartbeats representing premature atrial and ventricular contractions are common during childhood, with atrial ectopy predominating in infants and ventricular ectopy during adolescence. Isolated premature beats in patients with normal heart structure and function are usually benign.

**C. Axis**

1. **P-wave axis**—The P wave is generated from atrial contraction beginning in the high right atrium at the site of the sinus node. The impulse proceeds leftward and inferiorly, thus leading to a positive deflection in all left-sided and inferior leads (II, III, and aVF) and negative in lead aVR.

2. **QRS axis**—The net voltage should be positive in leads I and aVF in children with a normal axis. In infants and young children, RV dominance may persist, leading to a negative deflection in lead I. Several congenital cardiac lesions are associated with alterations in the normal QRS axis (Table 20–6).

**D. P Wave**

In the pediatric patient, the amplitude of the P wave is normally no greater than 3 mm and the duration no more than 0.08 second. The P wave is best seen in leads II and V1.

---

E. PR Interval
The PR is measured from the beginning of the P wave to the beginning of the QRS complex. It increases with age and with slower rates. The PR interval ranges from a minimum of 0.10 second in infants to a maximum of 0.18 second in older children with slow rates. Rheumatic heart disease, digitalis, β-blockers, and calcium channel blockers can prolong the PR interval.

F. QRS Complex
This represents ventricular depolarization, and its amplitude and direction of force (axis) reveal the relative ventricular mass in hypertrophy, hypoplasia, and infarction. Abnormal ventricular conduction (eg, right or left bundle-branch block) is also revealed.

G. QT Interval
This interval is measured from the beginning of the QRS complex to the end of the T wave. The QT duration may be prolonged as a primary condition or secondarily due to drugs or electrolyte imbalances (Table 20–7). The normal QT duration is rate-related and must be corrected using the Bazett formula:

$$QTc = \frac{QT \text{ interval (s)}}{\sqrt{R-R \text{ interval (s)}}}$$

The normal QTc is less than or equal to 0.44 second.

H. ST Segment
This segment, lying between the end of the QRS complex and the beginning of the T wave, is affected by drugs, electrolyte imbalances, or myocardial injury.

I. T Wave
The T wave represents myocardial repolarization and is altered by electrolytes, myocardial hypertrophy, and ischemia.
CHEST RADIOGRAPH

Evaluation of the chest radiograph for cardiac disease should focus on (1) position of the heart, (2) position of the abdominal viscera, (3) cardiac size, (4) cardiac configuration, and (5) character of the pulmonary vasculature. The standard posteroanterior and left lateral chest radiographs are used (Figure 20–2).

Cardiac position is either levocardia (heart predominantly in the left chest), dextrocardia (heart predominantly in the right chest), or mesocardia (midline heart). The position of the liver and stomach bubble is either in the normal position (abdominal situs solitus), inverted with the stomach bubble on the right (abdominal situs inversus), or variable with midline liver (abdominal situs ambiguous). The heart appears relatively large in normal newborns at least in part due to a prominent thymic shadow. The heart size should be less than 50% of the chest diameter in children older than age 1 year. The cardiac configuration on chest radiograph may provide useful diagnostic information (Table 20–8). Some congenital cardiac lesions have a characteristic radiographic appearance that suggests the diagnosis but should not be viewed as conclusive (Table 20–9). The pulmonary vasculature should be assessed. The presence of increased or decreased pulmonary blood flow suggests a possible congenital cardiac diagnosis, particularly in the cyanotic infant (Table 20–10).

Dextrocardia

Dextrocardia is a radiographic term used when the heart is on the right side of the chest. When dextrocardia occurs

which reflects off moving red blood cells. The transducer sends out a known frequency of sound and measures blood flow. The ultrasound construction of a two-dimensional image of the heart.

Ultrasound bursts across a 90-degree sector, which allows for cardiac function to be assessed. Echocardiography is based on the physical principles of sound waves. The ultrasound frequencies utilized in cardiac imaging range from 2 to 10 million cycles/s.

**M-mode** echocardiography uses short bursts of ultrasound sent from a transducer. At acoustic interfaces, sound waves are reflected back to the transducer. The time it takes for the sound wave to return to the transducer is measured and the distance to the interface is calculated. That calculated distance is displayed against time, and a one-dimensional image is constructed that demonstrates cardiac motion. **Two-dimensional imaging** extends this technique by sending a rapid series of ultrasound bursts across a 90-degree sector, which allows construction of a two-dimensional image of the heart. **Doppler ultrasound** measures blood flow. The ultrasound transducer sends out a known frequency of sound which reflects off moving red blood cells. The transducer receives the reflected frequency and compares it with the transmitted frequency. The blood flow velocity can be calculated from the measured frequency shift. This information is used to estimate pressure gradients by the simplified Bernoulli equation, in which the pressure gradient is equal to four times the calculated velocity (pressure gradient = 4V²).

A transthoracic echocardiogram is obtained by placing the transducer on areas of the chest where there is minimal lung interference. At each transducer position, the beam is swept through the heart and a two-dimensional image appears on the screen. Complex intracardiac anatomy and spatial relationships can be described, making possible the accurate diagnosis of congenital heart disease. In addition to structural details, Doppler gives information about intracardiac blood flow and pressure gradients. Commonly used Doppler techniques include color flow imaging, pulsed-wave, and continuous-wave Doppler. Color flow imaging gives general information on the direction and velocity of flow. Pulsed- and continuous-wave Doppler imaging give more precise measurements of blood velocity. The role of M-mode in the ultrasound examination has decreased as other ultrasound modalities have been developed. M-mode is still used to measure LV end-diastolic and end-systolic dimensions and permits calculation of the LV-shortening fraction, a standard estimate of LV function (SF = LV end-diastolic volume – LV systolic volume/LV end-diastolic volume). Three-dimensional echocardiography, tissue Doppler, strain, and strain rate imaging are newer modalities that provide more sophisticated assessment of systolic and diastolic function and can detect early changes in myocardial function.

A typical transthoracic echocardiogram performed by a skilled sonographer takes about 30 minutes, and patients must be still for the examination. Frequently infants and children cannot cooperate for the examination and sedation is required. Transesophageal echocardiography requires general anesthesia in infants and children and is primarily used to guide interventional procedures and surgical repair of congenital heart disease. In cases of difficult imaging windows due to patient size, air interference or when looking for evidence of vegetations on cardiac valves, transesophageal echocardiography may be necessary.

It is important to note that fetal echocardiography plays an important role in the prenatal diagnosis of congenital heart disease. A fetal echocardiogram is recommended if the fetus is considered high risk for the development of congenital heart disease or if there is suspicion for structural heart disease or fetal arrhythmias based on the obstetric fetal ultrasound. In utero management of fetal arrhythmias and post-delivery planning for the fetus with complex heart disease have resulted in improved outcomes for this challenging group of patients.

with reversal of position of the other important organs of the chest and abdomen (eg, liver, lungs, and spleen), the condition is called situs inversus totalis, and the heart is usually normal. When dextrocardia occurs with the other organs normally located (situs solitus), the heart usually has severe defects.

Other situs abnormalities include situs ambiguous with the liver central and anterior in the upper abdomen and the stomach pushed posteriorly; bilateral right-sidedness (asplenia syndrome); and bilateral left-sidedness (polysplenia syndrome). In virtually all cases of situs ambiguous, congenital heart disease is present.

**ECHOCARDIOGRAPHY**

Echocardiography is a fundamental tool of pediatric cardiology. Using multiple ultrasound modalities (two-dimensional imaging, Doppler, and M-mode), cardiac anatomy, blood flow, intracardiac pressures, and ventricular function can be assessed. Echocardiography is based on the physical principles of sound waves. The ultrasound frequencies utilized in cardiac imaging range from 2 to 10 million cycles/s.

Magnetic resonance imaging (MRI) of the heart is valuable for evaluation and noninvasive follow-up of many congenital heart defects. It is particularly useful in imaging the thoracic vessels, which are difficult to image by transthoracic echocardiogram. Cardiac gated imaging allows dynamic evaluation of structure and blood flow of the heart and great vessels. Cardiac MRI provides unique and precise imaging in patients with newly diagnosed or repaired aortic coarctation and defines the aortic dilation in Marfan, Turner, and Loeys-Dietz syndromes. Cardiac MRI can quantify regurgitant lesions such as pulmonary insufficiency (PI) after repair of tetralogy of Fallot (ToF) and can define ventricular function, chamber size, and wall thickness in patients with inadequate echocardiographic images or cardiomyopathies. MRI is especially useful to characterize right ventricular size and function as this chamber is often difficult to image comprehensively by echocardiogram. Because it allows computer manipulation of images of the heart and great vessels, three-dimensional MRI is an ideal noninvasive way of obtaining accurate reconstructions of the heart. General anesthesia is often required to facilitate cardiac MRI performance in children younger than 8 years.

Cardiopulmonary stress testing provides objective measurements in children with congenital cardiac lesions to ascertain limitations, develop exercise programs, assess effects of medical or surgical therapies, and determine need for cardiac transplantation. Most children with heart disease are capable of normal activity. Bicycle ergometers or treadmills can be used in children as young as age 5 years. The addition of a metabolic cart enables one to assess whether exercise impairment is secondary to cardiac limitation, pulmonary limitation, deconditioning, or lack of effort. Exercise variables include the ECG, blood pressure response to exercise, oxygen saturation, ventilation, maximal oxygen consumption, and peak workload attained. Stress testing is also employed in children with structurally normal hearts who have complaints of exercise-induced symptoms to rule out cardiac or pulmonary pathology. Significant stress ischemia or dysrhythmias warrant physical restrictions or appropriate therapy. Children with poor performance due to suboptimal conditioning benefit from a planned exercise program.

Quantitating the partial oxygen pressure (PO₂) or O₂ saturation during the administration of 100% oxygen is the most useful method of distinguishing cyanosis produced primarily by heart disease or by lung disease in sick infants. In cyanotic heart disease, the partial arterial oxygen pressure (PaO₂) increases very little when 100% oxygen is administered over the values obtained while breathing room air. However, PaO₂ usually increases significantly when oxygen is administered to a patient with lung disease. Table 20–11 illustrates the responses seen in patients with heart or lung disease during the hypoxic test. Although the US Department of Health and Human Services recommended newborn screening for critical congenital heart disease in 2010, implementation of comprehensive pulse oximetry screening programs are challenged by variable infrastructure and access to expert interpretation.

| Table 20–11. Examples of responses to 10 minutes of 100% oxygen in lung disease and heart disease. |
|-------------------------------------------------|-------------------------------------------------|
| Lung Disease | Heart Disease |
| Room Air | 100% O₂ | Room Air | 100% O₂ |
| Color | Blue → Pink | Blue → Blue |
| Oximetry | 60% → 99% | 60% → 62% |
| PaO₂ (mm Hg) | 35 → 120 | 35 → 38 |

PaO₂: partial arterial oxygen pressure.

CARDIOVASCULAR DISEASES

CARDIAC CATHETERIZATION & ANGIOCARDIOGRAPHY

Cardiac catheterization is an invasive method to evaluate anatomic and physiologic conditions in congenital or acquired heart disease. Management decisions may be made based on oximetric, hemodynamic, or angiographic data obtained through a catheterization. In an increasing number of cases, intervention may be performed during a catheterization that may palliate, or even cure, a congenital heart defect without open heart surgery.

Cardiac Catheterization Data

Figure 20–3 shows oxygen saturation (in percent) and pressure (in millimeters of mercury) values obtained at cardiac catheterization from the chambers and great arteries of the heart. These values represent the normal range for a school age child.

A. Oximetry, Shunts, and Cardiac Output

Measurement of oxygen levels throughout the heart and surrounding blood vessels can provide a wealth of information about a patient’s physiology. The difference between systemic saturation (in the aorta) and mixed venous saturation (usually in the superior vena cava [SVC]) is usually inversely proportional to the overall cardiac output. Cardiac output is determined by saturation difference across a vascular bed, taking into account oxygen consumption and hemoglobin. This is known as the Fick principle. Cardiac output in a healthy heart varies directly with the body’s oxygen consumption and is inversely proportional to hemoglobin. The circulatory system of patients who are anemic usually tries to generate a higher cardiac output to maintain oxygen delivery to the cells of the body.

An increase in saturation across the right side of the heart (anywhere between SVC and pulmonary arteries) represents a left-to-right shunt. If oxygenated blood can mix with venous blood, the saturation rises—the degree of which correlates with the size of the shunt. Conversely, a fall in saturation across the left heart, between the pulmonary veins and the aorta, is abnormal. This represents the addition of deoxygenated blood to oxygenated blood—a right-to-left shunt.

A commonly referenced ratio in pediatric cardiology is the Qp:Qs. In a normal heart, systemic cardiac output (Qs) and pulmonary blood flow (Qp) are equal, or Qp:Qs = 1. If a step-up in saturation is noted across the right heart, suggesting a left-to-right shunt, pulmonary blood flow will exceed systemic blood flow. This can result, in cases of large shunts, in a Qp:Qs of as high as 3:1 or more. This level of shunt is usually poorly tolerated, but small shunts (such as 1.5:1) may be well tolerated for months or years. In cases of right-to-left shunts, Qs will exceed Qp. In these cyanotic patients, the Qp:Qs may be 0.7 or 0.8.

B. Pressures

Pressures should be determined in all chambers and major vessels entered. Systolic pressure in the right ventricle should be equal to the systolic pressure in the pulmonary artery. Likewise, the systolic pressure in the left ventricle should be equal to the systolic pressure of the aorta. The mean pressure in the atria should be nearly equal to (or a point or two lower than) the end-diastolic pressure of the ventricles. If a gradient in pressure exists, an obstruction is present, and the severity of the gradient is one criterion for the necessity of intervention.

For example, a left ventricular systolic pressure in a small child of 140 mm Hg and an aortic systolic pressure of 80 mm Hg, a gradient of 60 mm Hg, would classify as severe aortic valve stenosis. Balloon aortic valvuloplasty would be indicated at the time of the catheterization.

▲ Figure 20–3. Pressures (mm Hg) and oxygen saturation (%) obtained by cardiac catheterization in a healthy child. 3, mean pressure of 3 mm Hg in the right atrium; 5, mean pressure of 5 mm Hg in the left atrium.
C. Vascular Resistance

In addition to pressure and flow, resistance completes the “concept triad” of congenital heart physiology. Resistance is related to pressure and flow as described in the below equation:

\[ \text{Resistance} = \frac{\text{Pressure}}{\text{Flow}} \]

The resistance across a vascular bed can be concretely calculated. Patients with congenital heart disease or pulmonary vascular disease may have elevation in pulmonary vascular resistance, which can adversely impact circulation and heart function. To calculate pulmonary vascular resistance, the pressure drop from the pulmonary arteries to the left atrium is divided by pulmonary blood flow (Qp) to obtain a value in units. For example, a patient with a mean pulmonary artery pressure of 15 mm Hg and a left atrial pressure of 9 mm Hg, with a Qp of 3 L/min/m², has a pulmonary vascular resistance of 2 U/m².

Normal pulmonary vascular resistance is less than 3 U/m². Systemic vascular resistance normally covers a wider range, usually from 10 to 30 U/m². The ratio of pulmonary to systemic vascular resistance is usually less than 0.3. High pulmonary resistance, or a high ratio of resistance, denotes abnormal pulmonary vasculature. It often represents increased risk in patients with congenital heart disease or pulmonary hypertension and results in higher risk of death in severely affected patients.

Cardiac catheterization can be performed to evaluate the effects of pharmaceutical therapy. An example of this use of catheterization is monitoring changes in pulmonary vascular resistance during the administration of nitric oxide or prostacyclin in a child with primary pulmonary hypertension.

Angiography

In the past, angiography was a mainstay of the initial diagnostic methods for congenital heart disease. It is still used for diagnostic purposes in selected cases, but currently is used more frequently to plan interventions or evaluate postsurgical anatomy that is poorly seen by noninvasive methods. Injection of contrast liquid via a well-positioned catheter can illuminate detailed intracardiac and intravascular anatomy more clearly than any other method. Cardiac function can be observed, and anatomic abnormalities may be easily identified. In a growing number of centers, three-dimensional reconstruction of angiograms can provide exquisite delineation of cardiac and vascular structures.

Interventional Cardiac Catheterization

Interventional cardiac catheterization procedures are performed to occlude lesions such as a patent ductus arteriosus, atrial septal defect, or ventricular septal defect. Obstruction of heart valves can be addressed through balloon valvuloplasty. Intervention may also be performed on vascular obstruction through angioplasty or stent placement in pulmonary arteries or the aorta. Systemic and pulmonary veins can be modified in a similar fashion, unfortunately with often minimal success in the latter. Devices are now available to allow patients to undergo replacement of failing heart valves without open heart surgery, and an increasing armamentarium of devices are becoming available for treatment of other defects and abnormal vasculature.

With the progression of improved noninvasive imaging, fewer diagnostic cardiac catheterization studies are performed today. The number of interventional procedures, however, is on the rise. Although the risks of cardiac catheterization are very low for elective studies in older children (< 1%), the risk of major complications in distressed or small patients is higher. Interventional procedures, particularly in unstable babies and children, increase these risks further. Increased use of registries is currently being employed to better understand efficacy rates and risks of these procedures, with the hope of optimizing the care of infants and children in the catheterization laboratory.

PERINATAL & NEONATAL CIRCULATION

At birth, two events affect the cardiovascular and pulmonary system: (1) the umbilical cord is clamped, removing the placenta from the maternal circulation and (2) breathing commences. As a result, marked changes in the circulation occur. During fetal life, the placenta offers low resistance to blood flow. In contrast, the pulmonary arterioles are markedly constricted and there is high resistance to blood flow in the lungs. Therefore, the majority of blood entering the right side of the heart travels from the right atrium into the left atrium across the foramen ovale (right-to-left shunt). In addition, most of the blood that makes its way into the right ventricle and then pulmonary arteries will flow from the pulmonary artery into the aorta through the ductus arteriosus (right-to-left shunt). Subsequently, pulmonary blood flow accounts for only 7%–10% of the combined in utero ventricular output. At birth, pulmonary blood flow dramatically increases with the fall in pulmonary vascular resistance and pressure. The causes of prolonged high pulmonary vascular resistance include physical factors (lack of an adequate air-liquid interface or ventilation), low oxygen tension, and vasoactive mediators such as elevated endothelin peptide levels or leukotrienes. Clamping the umbilical cord produces an immediate increase in resistance to flow in the systemic circuit.
As breathing commences, the $PO_2$ of the small pulmonary arterioles increases, resulting in a decrease in pulmonary vascular resistance. Increased oxygen tension, rhythmic lung distention, and production of nitric oxide as well as prostacyclin play major roles in the fall in pulmonary vascular resistance at birth. The pulmonary vascular resistance falls below that of the systemic circuit, resulting in a reversal in direction of blood flow across the ductus arteriosus and marked increase in pulmonary blood flow.

Functional closure of the ductus arteriosus begins shortly after birth. The ductus arteriosus usually remains patent for 1–5 days. During the first hour after birth, a small right-to-left shunt is present (as in the fetus). However, after 1 hour, bidirectional shunting occurs, with the left-to-right direction predominating. In most cases, right-to-left shunting disappears completely by 8 hours. In patients with severe hypoxia (eg, in the syndrome of persistent pulmonary hypertension of the newborn), pulmonary vascular resistance remains high, resulting in a continued right-to-left shunt. Although flow through the ductus arteriosus usually is gone by 5 days of life, the vessel does not close anatomically for 7–14 days.

In fetal life, the foramen ovale serves as a one-way valve shunting blood from the inferior vena cava through the right atrium into the left atrium. At birth, because of the changes in the pulmonary and systemic vascular resistance and the increase in the quantity of blood returning from the pulmonary veins to the left atrium, the left atrial pressure rises above that of the right atrium. This functionally closes the flap of the foramen ovale, preventing flow of blood across the septum. The foramen ovale remains probe patent in 10%–15% of adults.

Persistent pulmonary hypertension is a clinical syndrome of full-term infants. The neonate develops tachypnea, cyanosis, and pulmonary hypertension during the first 8 hours after delivery. These infants have massive right-to-left ductal and/or foramen shunting for 3–7 days because of high pulmonary vascular resistance. Progressive hypoxia and acidosis will cause early death unless the pulmonary resistance can be lowered. Postmortem findings include increased thickness of the pulmonary arteriolar media. Increased alveolar $PO_2$ with hyperventilation, alkalosis, paralysis, surfactant and decreased pulmonary vascular resistance. Increased oxygen tension, rhythmic lung distention, and production of nitric oxide as well as prostacyclin play major roles in the fall in pulmonary vascular resistance.

In the normal newborn, pulmonary vascular resistance and pulmonary arterial pressure continue to fall during the first weeks of life as a result of demuscularization of the pulmonary arterioles. Adult levels of pulmonary resistance and pressure are normally achieved by 4–6 weeks of age. It is at this time typically that signs of pulmonary overcirculation associated with left-to-right shunt lesions (VSD or atrioventricular septal defect [AVSD]) appear.

HEART FAILURE

Heart failure (HF) is the clinical condition in which the heart fails to meet the circulatory and metabolic needs of the body. Right and left heart failure can result from volume or pressure overload of the respective ventricle or an intrinsic abnormality of the ventricular myocardium. Causes of right ventricular volume overload include an ASD, PI, or anomalous pulmonary venous return. Left ventricular volume overload occurs with any left-to-right shunting lesion (eg, VSD, PDA), aortic insufficiency, or a systemic arteriovenous malformation. Causes of right ventricular failure as a result of pressure overload include pulmonary hypertension, valvar pulmonary stenosis, or severe branch pulmonary artery stenosis. Left ventricular pressure overload results from left heart obstructive lesions such as aortic stenosis (subvalvar, valvar, or supravalvar) or coarctation of the aorta. Abnormalities of the right ventricular myocardium that can result in right heart failure include Ebstein anomaly (atrialization of the right ventricle) and arrhythmogenic right ventricular dysplasia (a genetic disorder where the right ventricular myocardium is replaced by fat). Abnormalities of the left ventricular myocardium are more common and include dilated cardiomyopathy, myocarditis, or hypertrophic cardiomyopathy. As a result of elevated left atrial pressure and impaired relaxation of the left ventricle, left heart failure can lead to right heart failure. Other causes of HF in infants include AV septal defect, coronary artery anomalies, and chronic atrial tachyarrhythmias. Metabolic, mitochondrial, and neuromuscular disorders with associated cardiomyopathy can lead to right heart failure.

The therapy of HF should be directed toward the underlying cause as well as the symptoms. Regardless of the etiology, neurohormonal activation occurs early whenventricular systolic dysfunction is present. Plasma catecholamine levels (eg, norepinephrine) increase causing tachycardia, diaphoresis, and, by activating the renin-angiotensin system, peripheral vasoconstriction and salt and water retention. Treatment of pediatric HF is without much evidence basis. Therapies should be aimed at improving cardiac performance by targeting the three determinants of cardiac performance: (1) preload, (2) afterload, and (3) contractility.
Inpatient Management of Heart Failure

Patients with cardiac decompensation may require hospitalization for initiation or augmentation of HF therapy. Table 20–12 demonstrates intravenous inotropic agents used to augment cardiac output and their relative effect on heart rate, systemic vascular resistance, and cardiac index. The drug used will depend in part on the cause of the HF.

### A. Inotropic and Mechanical Support

#### 1. Afterload reduction

**A. Milrinone**—This phosphodiesterase-3 inhibitor increases cyclic adenosine monophosphate, thereby improving the inotropic state of the heart. In addition to a dose-dependent increase in cardiac contractility, milrinone is a systemic and pulmonary vasodilator and thus an effective agent in both right and left ventricular systolic dysfunction. Milrinone reduces the incidence of low cardiac output syndrome following open-heart surgery. The usual dosage range is 0.25–0.75 mcg/kg/min.

**B. Nitroglycerin**—Nitroglycerin functions primarily as a dilator of venous capacitance vessels and causes a reduction of right and left atrial pressure. Systemic blood pressure may also fall, and reflex tachycardia may occur. Nitroglycerin is used to improve coronary blood flow and may be especially useful when cardiac output is reduced because of coronary under-perfusion following congenital heart surgery. The usual intravenous dosage range is 1–3 mcg/kg/min.

#### 2. Enhancement of contractility

**A. Dopamine**—This naturally occurring catecholamine increases myocardial contractility primarily via cardiac β-adrenergic activation. Dopamine also directly acts on renal dopamine receptors to improve renal perfusion. The usual dose range for HF is 3–10 mcg/kg/min.

**B. Dobutamine**—This synthetic catecholamine increases myocardial contractility secondary to cardiospecific β-adrenergic activation and produces little peripheral vasoconstriction. Dobutamine does not usually cause marked tachycardia, which is a distinct advantage. However, the drug does not selectively improve renal perfusion as does dopamine. The usual dose range is essentially the same as for dopamine.

#### 3. Mechanical circulatory support

**Mechanical support** is indicated in children with severe, refractory myocardial failure secondary to cardiomyopathy, myocarditis, or following cardiac surgery. Mechanical support is used for a limited time while cardiac function improves or as a bridge to cardiac transplantation.

**A. Extracorporeal membrane oxygenation (ECMO)**—ECMO is a temporary means of providing oxygenation, carbon dioxide removal, and hemodynamic support to patients with cardiac or pulmonary failure refractory to conventional therapy. The blood removed from the patient via a catheter positioned in the venous system (eg, superior vena cava or right atrium) passes through a membrane oxygenator and then is delivered back to the patient through a catheter in the arterial system (eg, aorta or common carotid artery). The patient is monitored closely for improvement in cardiac contractility. Risks are significant and include severe internal and external bleeding, infection, thrombosis, and pump failure.

**B. Ventricular assist devices**—Use of ventricular assist devices is increasing in children as device development has progressed. These devices allow for less invasive hemodynamic support than ECMO. A cannula is usually positioned in the apex of the ventricle and removes blood from the ventricle using a battery-operated pump. Blood is then returned to the patient through a separate cannula positioned in the aorta or pulmonary artery, depending on the ventricle being used.
Outpatient Management of Heart Failure

A. Medications

1. Afterload-reducing agents—Oral afterload-reducing agents improve cardiac output by decreasing systemic vascular resistance. Angiotensin-converting enzyme (ACE) inhibitors (captopril, enalapril, and lisinopril) are first-line therapy in children with HF requiring long-term treatment. These agents block angiotensin II–mediated systemic vasoconstriction and are particularly useful in children with structurally normal hearts but reduced LV myocardial function (eg, myocarditis or dilated cardiomyopathies [DCMs]).

2. β-Blockade—Although clearly beneficial in adults with HF, a randomized, controlled study of the use of a β-blocker (carvedilol) in children with HF did not demonstrate any significant improvement compared to placebo. However, β-blockers may still be useful adjunctive therapy in some children with refractory HF already taking ACE inhibitors. In the setting of HF, excessive circulating catecholamines are present due to activation of the sympathetic nervous system. Although beneficial acutely, this compensatory response over time produces myocardial fibrosis, myocyte hypertrophy, and myocyte apoptosis that contribute to the progression of HF. β-Blockers (eg, carvedilol and metoprolol) antagonize this sympathetic activation and may offset these deleterious effects. Side effects of β-blockers include bradycardia, hypotension, and worsening HF in some patients.

3. Diuretics—Diuretic therapy may be necessary in HF to maintain the euvolemic state and control symptoms related to pulmonary or hepatic congestion.

a. Furosemide—This rapid-acting loop diuretic may be given intravenously or orally. It removes large amounts of potassium and chloride from the body, producing hypochloremic metabolic alkalosis when used chronically. Electrolytes should be monitored during long-term therapy.

b. Thiazides—Thiazides are distal tubular diuretics used to complement furosemide in severe cases of HF.

c. Spironolactone—Spironolactone is a potassium-sparing aldosterone inhibitor. It is used frequently in conjunction with furosemide or thiazides for its enhanced diuretic function. Because it spares potassium, supplemental potassium may be avoided. Spironolactone has benefit in adults with HF regardless of its diuretic effect as aldosterone is associated with the development of fibrosis, sodium retention, and vascular dysfunction. This effect has not been proven in children.

4. Digitalis—Digitalis is a cardiac glycoside with a positive inotropic effect on the heart and an associated decrease in systemic vascular resistance. The preparation of digitalis used in clinical practice is digoxin. Large studies in adult patients with HF have not demonstrated decreased mortality of HF with digoxin use, but treatment is associated with reduced hospitalization rates for HF exacerbations. There are no controlled studies in children.

a. Digitalis toxicity—Any dysrhythmia that occurs during digoxin therapy should be attributed to the drug until proven otherwise. Ventricular bigeminy and first-, second-, or third-degree AV block are characteristic of digoxin toxicity. A trough level should be obtained if digoxin toxicity is suspected.

b. Digitalis poisoning—This acute emergency must be treated without delay. Digoxin poisoning most commonly occurs in toddlers who have taken their parents’ or grandparents’ medications. The child’s stomach should be emptied immediately by gastric lavage even if several hours have passed since ingestion. Patients who have ingested massive amounts of digoxin should receive large doses of activated charcoal. In advanced heart block, atropine or temporary ventricular pacing may be needed. Digoxin immune Fab can be used to reverse potentially life-threatening intoxication. Antiarrhythmic agents may be useful.

early diagnosis, gene therapy, and recurrence risk counseling for families.

ACYANOTIC CONGENITAL HEART DISEASE

DEFECTS IN SEPTATION

1. Atrial Septal Defect

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Fixed, widely split $S_2$, RV heave.
- Grade I–III/VI systolic ejection murmur at the pulmonary area.
- Large shunts cause a diastolic flow murmur at the lower left sternal border (increased flow across the tricuspid valve).
- ECG shows $rsR'$ in lead $V_1$.
- Frequently asymptomatic.

General Considerations

Atrial septal defect (ASD) is an opening in the atrial septum permitting the shunting of blood between the atria. There are three major types: ostium secundum, ostium primum, and sinus venosus. Ostium secundum is the most common type and represents an embryologic deficiency in the septum secundum or too large of a central hole in the septum primum. Ostium primum defect is associated with atrioventricular septal defects. The sinus venosus defect is frequently associated with abnormal pulmonary venous return, as the location of the sinus venosus is intimately related to the right upper pulmonary vein.

Ostium secundum ASD occurs in 10% of patients with congenital heart disease and is two times more common in females than in males. The defect is most often sporadic but may be familial or have a genetic basis (Holt-Oram syndrome). After the third decade, atrial arrhythmias or pulmonary vascular disease may develop. Irreversible pulmonary hypertension resulting in cyanosis as atrial level shunting becomes right-to-left and ultimately right heart failure can occur and is a life-limiting process (Eisenmenger syndrome).

Clinical Findings

A. Symptoms and Signs

Most infants and children with an ASD have no cardiovascular symptoms. Older children and adults can present with exercise intolerance, easy fatigability, or, rarely, heart failure. The direction of flow across the ASD is determined by the compliance of the ventricles. Because the right ventricle is normally more compliant, shunting across the ASD is left-to-right as blood follows the path of least resistance. Therefore, cyanosis does not occur unless RV dysfunction occurs, usually as a result of pulmonary hypertension, leading to reversal of the shunt across the defect.

Peripheral pulses are normal and equal. The heart is usually hyperactive, with an RV heave felt best at the mid to lower left sternal border. $S_2$ at the pulmonary area is widely split and often fixed. In the absence of associated pulmonary hypertension, the pulmonary component is normal in intensity. A grade I–III/VI ejection-type systolic murmur is heard best at the left sternal border in the second intercostal space. This murmur is caused by increased flow across the pulmonic valve, not flow across the ASD. A mid-diastolic murmur is often heard in the fourth intercostal space at the left sternal border. This murmur is caused by increased flow across the tricuspid valve during diastole. The presence of this murmur suggests high flow with a pulmonary-to-systemic blood flow ratio greater than 2:1.

B. Imaging

Radiographs may show cardiac enlargement. The main pulmonary artery may be dilated and pulmonary vascular markings increased in large defects owing to the increased pulmonary blood flow.

C. Electrocardiography

The usual ECG shows right axis deviation. In the right precordial leads, an $rsR'$ pattern is usually present. A mutation in the cardiac homeobox gene ($NKX2-5$) is associated with an ASD, and AV block would be seen on the ECG.

D. Echocardiography

Echocardiography shows a dilated right atrium and RV. Direct visualization of the exact anatomic location of the ASD by two-dimensional echocardiography, and demonstration of a left-to-right shunt through the defect by color-flow Doppler, confirms the diagnosis and has eliminated the need for cardiac catheterization prior to surgical or catheter closure of the defect. Assessment of all pulmonary veins should be made to rule out associated anomalous pulmonary venous return.
E. Cardiac Catheterization

Although cardiac catheterization is rarely needed for diagnostic purposes, transcatheter closure of an ostium secundum ASD is now the preferred method of treatment.

If a catheterization is performed, oximetry shows a significant step-up in oxygen saturation from the superior vena cava to the right atrium. The pulmonary artery pressure and pulmonary vascular resistance are usually normal. The Qp:Qs may vary from 1.5:1 to 4:1.

Treatment

Surgical or catheterization closure is generally recommended for symptomatic children with a large atrial level defect and associated right heart dilation. In the asymptomatic child with a large hemodynamically significant defect, closure is performed electively at age 1–3 years. Most defects are amenable to nonoperative device closure during cardiac catheterization, but the defect must have adequate tissue rims on all sides on which to anchor the device. The mortality for surgical closure is less than 1%. When closure is performed by age 3 years, late complications of RV dysfunction and dysrhythmias are avoided.

Course & Prognosis

Patients usually tolerate an ASD well in the first two decades of life, and the defect often goes unnoticed until middle or late adulthood. Pulmonary hypertension and reversal of the shunt are rare late complications. Infective endocarditis (IE) is uncommon. Spontaneous closure occurs, most frequently in children with a defect less than 4 mm in diameter, therefore outpatient follow-up is recommended. Exercise tolerance and oxygen consumption in surgically corrected children are generally normal, and restriction of physical activity is unnecessary.

2. Ventricular Septal Defect

- Holosystolic murmur at lower left sternal border with RV heave.
- Presentation and course depend on size of defect and the pulmonary vascular resistance.

- Clinical features are failure to thrive, tachypnea, and diaphoresis with feeds.
- Left-to-right shunt with normal pulmonary vascular resistance.
- Large defects may cause Eisenmenger syndrome if not repaired early.

General Considerations

Ventricular septal defect (VSD) is the most common congenital heart malformation, accounting for about 30% of all congenital heart disease. Defects in the ventricular septum occur both in the membranous portion of the septum (most common) and the muscular portion. VSDs follow one of four courses:

A. Small, Hemodynamically Insignificant Ventricular Septal Defects

Between 80% and 85% of VSDs are small (< 3 mm in diameter) at birth and will close spontaneously. In general, small defects in the muscular interventricular septum will close sooner than those in the membranous septum. In most cases, a small VSD never requires surgical closure. Historically, in those who had cardiac catheterization, the ratio of pulmonary to systemic blood flow is usually less than 2:1, and serial cardiac catheterizations demonstrate that the shunts get progressively smaller. If the patient is asymptomatic and without evidence of pulmonary hypertension, these defects can be followed serially as some close spontaneously over time.

B. Moderate-Sized Ventricular Septal Defects

Asymptomatic patients with moderate-sized VSDs (3–5 mm in diameter) account for 3%–5% of children with VSDs. In general, these children do not have clear indicators for surgical closure. Historically, in those who had cardiac catheterization, the ratio of pulmonary to systemic blood flow is usually less than 2:1, and serial cardiac catheterizations demonstrate that the shunts get progressively smaller. If the patient is asymptomatic and without evidence of pulmonary hypertension, these defects can be followed serially as some close spontaneously over time.

C. Large Ventricular Septal Defects with Normal Pulmonary Vascular Resistance

These defects are usually 6–10 mm in diameter. Unless they become markedly smaller within a few months after birth, they often require surgery. The timing of surgery depends on the clinical situation. Many infants with large VSDs and normal pulmonary vascular resistance develop symptoms of failure to thrive, tachypnea, diaphoresis with feeds by age 3–6 months, and require correction at that time. Surgery before age 2 years in patients with large VSDs essentially eliminates the risk of pulmonary vascular disease.
D. Large Ventricular Septal Defects with Pulmonary Vascular Obstructive Disease

The direction of flow across a VSD is determined by the resistance in the systemic and pulmonary vasculature, explaining why flow is usually left-to-right. In large VSDs, ventricular pressures are equalized, resulting in increased pulmonary artery pressure. In addition, shear stress caused by increased volume in the pulmonary circuit causes increased resistance over time. The vast majority of patients with inoperable pulmonary hypertension develop the condition progressively. The combined data of the multicenter National History Study indicate that almost all cases of irreversible pulmonary hypertension can be prevented by surgical repair of a large VSD before age 2 years.

Clinical Findings

A. Symptoms and Signs

Patients with small or moderate left-to-right shunts usually have no cardiovascular symptoms. Patients with large left-to-right shunts are usually ill early in infancy. These infants have frequent respiratory infections and gain weight slowly. Dyspnea, diaphoresis, and fatigue are common. These symptoms can develop as early as 1–6 months of age. Older children may experience exercise intolerance. Over time, in children and adolescents with persistent large left-to-right shunt, the pulmonary vascular bed undergoes structural changes, leading to increased pulmonary vascular resistance and reversal of the shunt from left-to-right to right-to-left (Eisenmenger syndrome). Cyanosis will then be present.

1. Small left-to-right shunt—No lifts, heaves, or thrills are present. The first sound at the apex is normal, and the second sound at the pulmonary area is split physiologically. A grade II–IV/VI, medium- to high-pitched, harsh pansystolic murmur is heard best at the left sternal border in the third and fourth intercostal spaces. The murmur radiates over the entire precordium. No diastolic murmurs are heard.

2. Moderate left-to-right shunt—Slight prominence of the precordium with moderate LV heave is evident. A systolic thrill may be palpable at the lower left sternal border between the third and fourth intercostal spaces. The second sound at the pulmonary area is most often split but may be single. A grade III–IV/VI, harsh pansystolic murmur is heard best at the lower left sternal border in the fourth intercostal space. A mitral diastolic flow murmur indicates that pulmonary blood flow and subsequently the pulmonary venous return are significantly increased by the large shunt.

3. Large ventricular septal defects with pulmonary hypertension—The precordium is prominent, and the sternum bulges. Both LV and RV heaves are palpable. S₂ is palpable in the pulmonary area. A thrill may be present at the lower left sternal border. S₁ is usually single or narrowly split, with accentuation of the pulmonary component. The murmur ranges from grade I to IV/VI and is usually harsh and pansystolic. Occasionally, when the defect is large or ventricular pressures approach equivalency, a murmur is difficult to hear. A diastolic flow murmur may be heard, depending on the size of the shunt.

B. Imaging

In patients with small shunts, the chest radiograph may be normal. Patients with large shunts have significant cardiac enlargement involving both the left and right ventricles and the left atrium. The main pulmonary artery segment may be dilated. The pulmonary vascular markings are increased.

C. Electrocardiography

The ECG is normal in small left-to-right shunts. Left ventricular hypertrophy (LVH) usually occurs in patients with large left-to-right shunts and normal pulmonary vascular resistance. Combined ventricular enlargement occurs in patients with pulmonary hypertension caused by increased flow, increased resistance, or both. Pure RV hypertrophy occurs in patients with pulmonary hypertension secondary to pulmonary vascular obstruction induced by long standing left to right shunt (Eisenmenger syndrome).

D. Echocardiography

Two-dimensional echocardiography can reveal the size of a VSD and identify its anatomic location. Multiple defects can be detected by combining two-dimensional and color-flow imaging. Doppler can further evaluate the VSD by estimating the pressure difference between the left and right ventricles. A pressure difference greater than 50 mm Hg in the left ventricle compared to the right ventricle confirms the absence of severe pulmonary hypertension.

E. Cardiac Catheterization and Angiocardiography

The ability to describe the VSD anatomy and estimate the pulmonary artery pressures on the basis of the gradient across the VSD allows for the vast majority of isolated defects to be repaired without cardiac catheterization and angiocardiography. Catheterization is indicated in those patients with increased pulmonary vascular resistance. Angiocardiographic examination defines the number, size, and location of the defects.

Treatment

A. Medical Management

Patients who develop symptoms can be managed with anti-congestive treatment, particularly diuretics and systemic
afterload reduction, prior to surgery or if it is expected that the defect will close over time.

B. Surgical Treatment

Patients with cardiomegaly, poor growth, poor exercise tolerance, or other clinical abnormalities who have a significant shunt (> 2:1) typically undergo surgical repair at age 3–6 months. A synthetic or pericardial patch is used for primary closure. In most centers, these children have surgery before age 1 year. As a result, Eisenmenger syndrome has been virtually eliminated. The surgical mortality rate for VSD closure is below 2%.

Transcatheter closure of muscular VSDs is also a possibility. Perimembranous VSDs have also been closed in children during catheterization, but a high incidence of complete heart block after placement of the occluding device has slowed the acceptance of this approach.

Course & Prognosis

Significant late dysrhythmias are uncommon. Functional exercise capacity and oxygen consumption are usually normal, and physical restrictions are unnecessary. Adults with corrected defects have normal quality of life.

3. Atrioventricular Septal Defect

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Murmur often inaudible in neonates.
- Loud pulmonary component of S2.
- Common in infants with Down syndrome.
- ECG with extreme left axis deviation.

General Considerations

Atrioventricular septal defect (AVSD) results from incomplete fusion of the embryonic endocardial cushions. The endocardial cushions help to form the “crux” of the heart, which includes the lower portion of the atrial septum, the membranous portion of the ventricular septum, and the septal leaflets of the tricuspid and mitral valves. AVSD accounts for about 4% of all congenital heart disease. Sixty percent of children with Down syndrome have congenital heart disease, and of these, 35%–40% have an AVSD.

AVSDs are defined as partial or complete. The physiology of the defect is determined by the location of the AV valves. If the valves are located in the midportion of the defect (complete AVSD), both atrial and ventricular components of the septal defect are present and the left- and right-sided AV valves share a common ring or orifice. In the partial form, there is a low insertion of the AV valves, resulting in a primum ASD without a ventricular defect component. In partial AVSD, there are two separate AV valve orifices and usually a cleft in the left-sided valve.

Partial AVSD behaves like an isolated ASD with variable amounts of regurgitation through the cleft in the left AV valve. The complete form causes large left-to-right shunts at both the ventricular and atrial levels with variable degrees of AV valve regurgitation. If there is increased pulmonary vascular resistance, the shunts may be bidirectional. Bidirectional shunting is more common in Down syndrome or in older children who have not undergone repair.

Clinical Findings

A. Symptoms and Signs

The partial form may produce symptoms similar to ostium secundum ASD. Patients with complete AVSD usually have symptoms such as failure to thrive, tachypnea, diaphoresis with feeding, or recurrent bouts of pneumonia.

In the neonate with the complete form, the murmur may be inaudible due to relatively equal systemic and pulmonary vascular resistance (PVR). After 4–6 weeks, as PVR drops, a nonspecific systolic murmur develops. The murmur is usually not as harsh as that of an isolated VSD. There is both right- and left-sided cardiac enlargement. S2 is loud, and a pronounced diastolic flow murmur may be heard at the apex and the lower left sternal border.

If severe pulmonary vascular obstructive disease is present, there is usually dominant RV enlargement. S2 is palpable at the pulmonary area and no thrill is felt. A nonspecific short systolic murmur is heard at the lower left sternal border. No diastolic flow murmurs are heard. If a right-to-left shunt is present, cyanosis will be evident.

B. Imaging

Cardiac enlargement is always present in the complete form and pulmonary vascular markings are increased. Often, only the right heart size may be increased in the partial form, although a severe mitral valve cleft can rarely lead to left heart enlargement as well.
C. Electrocardiography
In all forms of AVSD, there is extreme left axis deviation with a counterclockwise loop in the frontal plane. The ECG is an important diagnostic tool. Only 5% of isolated VSDs have this ECG abnormality. First-degree heart block occurs in over 50% of patients. Right, left, or combined ventricular hypertrophy is present depending on the particular defect and the presence or absence of pulmonary hypertension.

D. Echocardiography
Echocardiography is the diagnostic test of choice. The anatomy can be well visualized by two-dimensional echocardiography. Both AV valves are at the same level, compared with the normal heart in which the tricuspid valve is more apically positioned. The size of the atrial and ventricular components of the defect can be measured. AV valve regurgitation can be detected. The LV outflow tract is elongated (gooseneck appearance), which produces systemic outflow obstruction in some patients.

E. Cardiac Catheterization and Angiocardiography
Cardiac catheterization is not routinely used to evaluate AVSD but may be used to assess pulmonary artery pressures and resistance in the older infant with Down syndrome, as this patient group is predisposed to early-onset pulmonary hypertension. Increased oxygen saturation in the RV or the right atrium identifies the level of the shunt. Angiocardiography reveals the characteristic gooseneck deformity of the LV outflow tract in the complete form.

Treatment
Spontaneous closure of this type of defect does not occur and therefore surgery is required. In the partial form, surgery carries a low mortality rate (1%–2%), but patients require follow-up because of late-occurring LV outflow tract obstruction and mitral valve dysfunction. The complete form carries a higher mortality rate. Complete correction in the first year of life, prior to the onset of irreversible pulmonary hypertension, is obligatory.

PATENT (PERSISTENT) DUCTUS ARTERIOSUS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Continuous machinery type murmur.
- Bounding peripheral pulses if large ductus present.
- Presentation and course depends on size of the ductus and the pulmonary vascular resistance.
- Clinical features of a large ductus are failure to thrive, tachypnea, and diaphoresis with feeds.
- Left-to-right shunt with normal pulmonary vascular resistance.

General Considerations
PDA is the persistence of the normal fetal vessel joining the pulmonary artery to the aorta. It closes spontaneously in normal-term infants at 1–5 days of age. PDA accounts for 10% of all congenital heart disease. The incidence of PDA is higher in infants born at altitudes over 10,000 ft. It is twice as common in females as in males. The frequency of PDA in preterm infants weighing less than 1500 g ranges from 20% to 60%. The defect may occur as an isolated abnormality or with associated lesions, commonly coarctation of the aorta and VSD. Patency of the ductus arteriosus may be necessary in some patients with complex forms of congenital heart disease (eg, hypoplastic left heart syndrome [HLHS], pulmonary atresia). Prostaglandin E2 (PGE2) is a product of arachidonic acid metabolism and continuous intravenous infusion maintains ductal patency.

Clinical Findings
A. Symptoms and Signs
The clinical findings and course depend on the size of the shunt and the degree of pulmonary hypertension.

1. Moderate to large patent ductus arteriosus—Pulses are bounding, and pulse pressure is widened due to diastolic runoff through the ductus. 
S1 is normal and S2 is usually narrowly split. In large shunts, S2 may have a paradoxical split (eg, S2 narrows on inspiration and widens on expiration). Paradoxical splitting is caused by volume overload of the LV and prolonged ejection of blood from this chamber.

The murmur is characteristic. It is a rough machinery murmur maximal at the second left intercostal space. It begins shortly after S1, rises to a peak at S2, and passes through the S2 into diastole, where it becomes a decrescendo murmur and fades before the S1. The murmur tends to

Craig B: Atrioventricular septal defect: from fetus to adult. Heart 2006;92:1879–1885 [PMID: 17105897].
radiate well to the anterior lung fields but relatively poorly to the posterior lung fields. A diastolic flow murmur is often heard at the apex.

2. **Patent ductus arteriosus with increased pulmonary vascular resistance**—Flow across the ductus is diminished. S₂ is single and accentuated, and no significant heart murmur is present. The pulses are normal rather than bounding.

**B. Imaging**

In an isolated PDA, the appearance of the chest radiograph depends on the size of the shunt. If the shunt is small, the heart is not enlarged. If the shunt is large, both left atrial and LV enlargement may be seen. The aorta and the main pulmonary artery segment may also be prominent.

**C. Electrocardiography**

The ECG may be normal or may show LVH, depending on the size of the shunt. In patients with pulmonary hypertension caused by increased blood flow, biventricular hypertrophy usually occurs. In pulmonary vascular obstructive disease, pure right ventricular hypertrophy (RVH) occurs.

**D. Echocardiography**

Echocardiography provides direct visualization of the ductus and confirms the direction and degree of shunting. High-velocity left-to-right flow argues against abnormally elevated pulmonary vascular resistance, and as pulmonary vascular resistance drops during the neonatal period, higher velocity left-to-right shunting is usually seen. If suprasystemic pulmonary vascular resistance is present, flow across the ductus will be seen from right to left. Associated cardiac lesions and ductal-dependent pulmonary or systemic blood flow must be recognized by echocardiography, as closure of a PDA in this setting would be contraindicated.

**E. Cardiac Catheterization and Angiocardiography**

PDA closure in the catheterization laboratory with a vascular plug or coils is now routine in all but the smallest of neonates and infants.

**Treatment**

Surgical closure is indicated when the PDA is large and the patient is small. Caution must be given to closing a PDA in patients with pulmonary vascular obstructive disease and right-to-left shunting across the ductus as this could result in RV failure. Patients with large left-to-right shunts require repair by age 1 year to prevent the development of progressive pulmonary vascular obstructive disease. Symptomatic PDA with normal pulmonary artery pressure can be safely coil or device-occluded in the catheterization laboratory, ideally after the child has reached 5 kg.

Patients with nonreactive pulmonary vascular obstruction, pulmonary vascular resistance greater than 10 Wood units (normal, < 3), and a ratio of pulmonary to systemic resistance greater than 0.7 (normal, < 0.3) despite vasodilator therapy (eg, nitric oxide) should not undergo PDA closure. These patients are made worse by PDA closure because the flow through the ductus allows preserved RV function and maintains cardiac output to the systemic circulation. These patients can be managed with pulmonary vasodilator therapy, but eventually may require heart-lung transplant in severe cases.

Presence of a symptomatic PDA is common in preterm infants. Indomethacin, a prostaglandin synthesis inhibitor, is often used to close the PDA in premature infants. Indomethacin does not close the PDA of full-term infants or children. The success of indomethacin therapy is as high as 80%–90% in premature infants with a birth weight greater than 1200 g, but it is less successful in smaller infants. Indomethacin (0.1–0.3 mg/kg orally every 8–24 hours or 0.1–0.3 mg/kg parenterally every 12 hours) can be used if there is adequate renal, hematologic, and hepatic function. Because indomethacin may impair renal function, urine output, BUN, and creatinine should be monitored during therapy. If indomethacin is not effective and the ductus remains hemodynamically significant, surgical ligation should be performed. If the ductus partially closes so that the shunt is no longer hemodynamically significant, a second course of indomethacin may be tried.

**Course & Prognosis**

Patients with an isolated PDA and small-to-moderate shunts usually do well without surgery. However, in the third or fourth decade of life, symptoms of easy fatigability, dyspnea on exertion, and exercise intolerance appear in those patients who develop pulmonary hypertension and/or HF. Percutaneous closure can be done later in life if there has not been development of severe pulmonary vascular disease. For those with severe and irreversible pulmonary hypertension prognosis is not good and heart-lung transplant may be needed.

Spontaneous closure of a PDA may occur up to age 1 year, especially in preterm infants. After age 1 year, spontaneous closure is rare. Because endocarditis is a potential complication, some cardiologists recommend closure if the defect persists beyond age 1 year, even if it is small. Most of these patients undergo percutaneous occlusion as opposed to surgical ligation.
CHAPTER 20

RIGHT-SIDED OBSTRUCTIVE LESIONS

1. Pulmonary Valve Stenosis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► No symptoms in mild or moderate stenosis.
► Cyanosis and a high incidence of right-sided HF in ductal-dependent lesions.
► RV lift with systolic ejection click heard at the third left intercostal space.
► S2 widely split with soft to inaudible P2; grade I–VI systolic ejection murmur, maximal at the pulmonary area.
► Dilated pulmonary artery on chest radiograph.

General Considerations

Pulmonic valve stenosis accounts for 10% of all congenital heart disease. The pulmonary valve annulus is usually small with moderate to marked poststenotic dilation of the main pulmonary artery. Obstruction to blood flow across the pulmonary valve causes an increase in RV pressure. Pressures greater than systemic are potentially life-threatening and are associated with critical obstruction. Because of the increased RV strain, severe right ventricular hypertrophy (RVH) and eventual RV failure can occur.

When obstruction is severe and the ventricular septum is intact, a right-to-left shunt will often occur at the atrial level through a patent foramen ovale (PFO). In neonates with severe obstruction and minimal antegrade pulmonary blood flow (critical PS), left-to-right flow through the ductus is essential, making prostaglandin a necessary intervention at the time of birth. These infants are cyanotic at presentation.

Clinical Findings

A. Symptoms and Signs

Patients with mild or even moderate valvular pulmonary stenosis are acyanotic and asymptomatic. Patients with severe valvular obstruction may develop cyanosis early. Patients with mild to moderate obstruction are usually well developed and well nourished. They are not prone to pulmonary infections. The pulses are normal. The precordium may be prominent, often with palpable RV heave. A systolic thrill is often present in the pulmonary area. In patients with mild to moderate stenosis, a prominent ejection click of pulmonary origin is heard at the third left intercostal space. The click varies with respiration, being more prominent during expiration than inspiration. In severe stenosis, the click tends to merge with S1. S2 varies with the degree of stenosis. In mild pulmonic stenosis, S2 is normal. In moderate pulmonic stenosis, S2 is more widely split and the pulmonary component is softer. In severe pulmonary stenosis, S2 is single because the pulmonary component cannot be heard. A rough systolic ejection murmur is best heard at the second left interspace. It radiates well to the back. With severe pulmonic valve obstruction, the murmur is usually short. No diastolic murmurs are audible.

B. Imaging

The heart size is normal. Poststenotic dilation of the main pulmonary artery and the left pulmonary artery often occurs.

C. Electrocardiography

The ECG is usually normal with mild obstruction. In severe obstruction, RV hypertrophy with an RV strain pattern (deep inversion of the T wave) occurs in the right precordial leads (V3R, V1, V2). Right atrial enlargement may be present. Right axis deviation occurs in moderate to severe stenosis.

D. Echocardiography

The diagnosis often is made by physical examination, but the echocardiogram confirms the diagnosis, defines the anatomy, and can identify any associated lesions. The pulmonary valve has thickened leaflets with reduced valve leaflet excursion. The transvalvular pressure gradient can be estimated accurately by Doppler, which provides an estimate of RV pressure and can assist in determining the appropriate time to intervene.

E. Cardiac Catheterization and Angiocardiography

Catheterization is reserved for therapeutic balloon valvuloplasty. In severe cases with associated RV dysfunction, a right-to-left shunt at the atrial level is indicated by a lower left atrial saturation than pulmonary vein saturation. Pulmonary artery pressure is normal. The gradient across the pulmonary valve varies from 10 to 200 mm Hg. In severe cases, the right atrial pressure is elevated, with a predominant “a” wave. Angiocardiography in the RV shows a thick pulmonary valve with a narrow opening producing a jet of contrast into the pulmonary artery. Infundibular (RV outflow tract) hypertrophy may be present and may contribute to obstruction to pulmonary blood flow.
3. Supravalvular Pulmonary Stenosis

Supravalvular pulmonary stenosis is a relatively rare condition defined by narrowing of the main pulmonary artery. The clinical picture may be identical to valvular pulmonary stenosis, although the murmur is maximal in the first intercostal space at the left sternal border and in the suprasternal notch. No ejection click is audible, as the valve itself is not involved. The murmur radiates toward the neck and over the lung fields. Children with William syndrome can have supravalvular and peripheral pulmonary stenosis as well as supravalvular aortic stenosis.

4. Peripheral (Branch) Pulmonary Artery Stenosis

In peripheral pulmonary stenosis, there are multiple narrowings of the branches of the pulmonary arteries, sometimes extending into the vessels in the periphery of the lungs. Systolic murmurs may be heard over both lung fields, anteriorly and posteriorly, radiating to the axilla. Mild, nonpathologic pulmonary branch stenosis produces a murmur in infancy that resolves by 6 months of age. William syndrome, Alagille syndrome, and congenital rubella are commonly associated with severe forms of peripheral pulmonary artery stenosis. Surgery is often unsuccessful, as areas of stenoses near and beyond the hilum of the lungs are not accessible to the surgeons. Transcatheter balloon angioplasty and even stent placement are used to treat this condition, with moderate success. In some instances, the stenoses improve spontaneously with age.

5. Ebstein Malformation of the Tricuspid Valve

In Ebstein malformation of the tricuspid valve, the septal leaflet of the tricuspid valve is displaced toward the apex of the heart and is attached to the endocardium of the RV rather than at the tricuspid annulus. As a result, a large portion of the RV functions physiologically as part of the right atrium. This “atrialized” portion of the RV is thin-walled and does not contribute to RV output. The portion of the ventricle below the displaced tricuspid valve is diminished in volume and represents the functioning RV.

A. Symptoms and Signs

The clinical picture of Ebstein malformation varies with the degree of displacement of the tricuspid valve. In the most extreme form, the septal leaflet is markedly displaced into the RV outflow tract, causing obstruction of antegrade flow into the pulmonary artery and there is very little functioning RV as the majority of the ventricle is “atrialized.” The degree of tricuspid insufficiency may be so severe that forward (antegrade)
flow out the RV outflow tract is further diminished leading to a right-to-left atrial level shunt and cyanosis. At the opposite extreme when antegrade pulmonary blood flow is adequate, symptoms may not develop until adulthood when tachyarhythmias associated with right atrial dilation or reentrant electrical pathways occur. These older patients typically have less displacement of the septal leaflet of the tricuspid valve and therefore more functional RV tissue.

B. Imaging
The chest radiograph shows cardiomegaly with prominence of the right heart border. The extent of cardiomegaly depends on the degree of tricuspid valve insufficiency and the presence and size of the atrial level shunt. Massive cardiomegaly with a “wall-to-wall heart” (the heart shadow extends across the entire chest cavity from right-to-left) occurs with severe tricuspid valve displacement and/or a restrictive atrial level defect.

C. Electrocardiography
ECG may be normal but usually shows right atrial enlargement and right bundle-branch block (RBBB). There is an association between Ebstein anomaly and Wolff-Parkinson-White (WPW) syndrome, in which case a delta wave is present (short PR with a slurred upstroke of the QRS).

D. Echocardiography
Echocardiography is necessary to confirm the diagnosis and may aid in predicting outcome. Degree of tricuspid valve displacement, size of the right atrium, and presence of associated atrial level shunt all affect outcome.

Course & Prognosis
In cyanotic neonates, PGE₂ is used to maintain pulmonary blood flow via the ductus arteriosus until pulmonary vascular resistance decreases, facilitating antegrade pulmonary artery flow. If the neonate remains significantly cyanotic, surgical intervention is required.

The type of surgical repair varies and depends on the severity of the disease. For example, in order to decrease the amount of tricuspid regurgitation surgery may involve atrial plication and tricuspid valve repair. The success of the procedure is highly variable. Late arrhythmias are common due to the preexisting atrial dilation. If a significant Ebstein malformation is not treated, atrial tachyarrhythmias frequently begin during adolescence and the enlarged atrialized RV could impede LV function. Postoperative exercise tolerance improves but remains lower than age-related norms.

LEFT-SIDED LESIONS

1. Coarctation of the Aorta

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► Absent or diminished femoral pulses.
► Upper to lower extremity systolic blood pressure gradient of > 20 mm Hg.
► Blowing systolic murmur in the back or left axilla.

General Considerations
Coarctation of the aorta is a narrowing in the aortic arch that usually occurs in the proximal descending aorta near the takeoff of the left subclavian artery near the ductus arteriosus. The abdominal aorta is rarely involved. Coarctation accounts for about 6% of all congenital heart disease. Three times as many males as females are affected. Many affected females have Turner syndrome (45, XO). The incidence of associated bicuspid aortic valve with coarctation is 80%–85%.

Clinical Findings

A. Symptoms and Signs
The cardinal physical finding is decreased or absent femoral pulses. Infants with severe coarctation have equal upper and lower extremity pulses from birth until the ductus arteriosus closes (ductal patency ensures flow to the descending aorta distal to the level of obstruction). Approximately 40% of children with coarctation will present as young infants. Coarctation alone, or in combination with VSD, ASD, or other congenital cardiac anomalies, is the leading cause of HF in the first month of life.

Coarctation presents insidiously in the 60% of children with no symptoms in infancy. Coarctation is usually diagnosed by a pulse and blood pressure (> 15 mm Hg) discrepancy between the arms and legs on physical examination. The pulses in the legs are diminished or absent. The left subclavian artery is occasionally involved in the coarctation, in which case the left brachial pulse is also weak. The pathognomonic murmur of coarctation is heard in the left axilla and the left back. The murmur is usually systolic but may spill into diastole, as forward flow continues across the narrow coarctation site throughout the cardiac cycle. A systolic ejection murmur is often heard at the aortic area and the lower left sternal border along with an apical ejection click if there is an associated bicuspid aortic valve.
B. Imaging
In the older child, radiographs may show a normal-sized heart, or more often some degree of LV enlargement. The aorta proximal to the coarctation is prominent. The poststenotic segment is often dilated. This combination of abnormalities results in the “figure 3” sign on chest radiograph. Notching of the ribs caused by marked enlargement of the intercostal collaterals can be seen. In patients with severe coarctation and associated HF, marked cardiac enlargement and pulmonary venous congestion occur.

C. Electrocardiography
ECGs in older children may be normal or may show LVH. ECG usually shows RVH in infants with severe coarctation because the RV serves as the systemic ventricle during fetal life.

D. Echocardiography
Two-dimensional echocardiography and color-flow Doppler are used to visualize the coarctation directly, and continuous-wave Doppler estimates the degree of obstruction. Diastolic runoff flow is detected by continuous-wave Doppler if the obstruction is significant. In neonates with a PDA, a coarctation cannot be ruled out, as stenosis of the arch may evolve as the PDA closes. Identification of lesions such as a bicuspid aortic valve or mitral abnormalities may suggest the presence of a coarctation. In the face of poor LV systolic function, the gradient across the coarctation will be low, as the failing LV is unable to generate very much pressure proximal to the narrowing.

E. Cardiac Catheterization and Angiography
Cardiac catheterization and angiography are rarely performed for diagnosis in infants or children with coarctation, but are used if transcatheter intervention is planned.

Treatment
Infants with coarctation of the aorta and HF may present in extremis secondary to LV dysfunction and low cardiac output. Resuscitative measures include PGE2 infusion (0.05–0.1 mcg/kg/min) to reopen the ductus arteriosus. End-organ damage distal to the coarctation is not uncommon, and inotropic support is frequently needed. Once stabilized, the infant should undergo corrective repair. In patients with poor LV function, balloon angioplasty of the coarctation is sometimes performed as a palliative measure. Recent data suggest that balloon angioplasty of the aorta can be the definitive procedure in many patients with good LV function. Surgery also has a high success rate. The main complication of both surgery and balloon angioplasty is recurrent coarctation. Fortunately, this complication is treatable in the catheterization laboratory. In older patients, particularly those of adult size, transcatheter stent placement is effective for recurrent coarctation.

Course & Prognosis
Children who survive the neonatal period without developing HF do well through childhood and adolescence. Fatal complications (eg, hypertensive encephalopathy or intracranial bleeding) are uncommon in childhood. Infective endarteritis is rare before adolescence, but can occur in both repaired and unrepaired coarctation. Children with coarctation corrected after age 5 years are at increased risk for systemic hypertension and myocardial dysfunction even with successful surgery. Exercise testing is mandatory for these children prior to their participation in athletic activities.

2. Aortic Stenosis

</tbody>
</table>

General Considerations
Aortic stenosis is defined as obstruction to outflow from the LV at or near the aortic valve producing a systolic pressure gradient of more than 10 mm Hg between the LV and the aorta. Aortic stenosis accounts for approximately 7% of congenital heart disease. There are three anatomic types of congenital aortic stenosis.
A. Valvular Aortic Stenosis (75%)

In critical aortic stenosis presenting in infancy, the aortic valve is usually a unicuspid diaphragm-like structure without well-defined commissures. A bicuspid aortic valve or a trileaflet valve with partially fused leaflets is another anatomic possibility that can be associated with aortic stenosis. Aortic stenosis is more common in males than in females.

B. Subvalvular Aortic Stenosis (23%)

In this type, a membranous or fibrous ring occurs just below the aortic valve that causes obstruction to LV outflow. The aortic valve itself and the anterior leaflet of the mitral valve are often malformed.

C. Supravalvular Aortic Stenosis (2%)

In this type, constriction of the ascending aorta occurs just above the coronary arteries. The condition is often familial, and two different genetic patterns are found, one with abnormal facies and mental retardation (William syndrome) and other with normal facies and no developmental delay.

Clinical Findings

A. Symptoms and Signs

Although isolated valvular aortic stenosis seldom causes symptoms in infancy, severe HF occasionally occurs when critical obstruction is present at birth. Response to medical therapy is poor; therefore, an aggressive approach using interventional catheterization or surgery is required. The physical findings vary depending on the anatomic type of lesion:

1. Valvular aortic stenosis—If the stenosis is severe with a gradient greater than 80 mm Hg, pulses are diminished with a slow upstroke; otherwise, pulses are usually normal. Cardiac examination reveals an LV thrust at the apex. A systolic thrill at the right base, the suprasternal notch, and over both carotid arteries may accompany moderate disease.

   A prominent aortic ejection click is best heard at the apex. The click corresponds to the opening of the aortic valve. It is separated from S1 by a short but appreciable interval. It does not vary with respiration. S2 at the pulmonary area is normal. A loud, rough, medium- to high-pitched ejection-type systolic murmur is evident. It is loudest at the first and second intercostal spaces, radiating well into the suprasternal notch and along the carotids. The grade of the murmur correlates well with the severity of the stenosis.

2. Discrete membranous subvalvular aortic stenosis—The findings are the same as those of valvular aortic stenosis except for the absence of a click.

The murmur and thrill are usually somewhat more intense at the left sternal border in the third and fourth intercostal spaces. In the setting of aortic insufficiency, a diastolic murmur is commonly heard.

3. Supravalvular aortic stenosis—The thrill and murmur are best heard in the suprasternal notch and along the carotids but are well transmitted over the aortic area and near the mid left sternal border. There may be a difference in pulses and blood pressure between the right and left arms if the narrowing is just distal to the takeoff of the innominate artery, with more prominent pulse and pressure in the right arm (the Coanda effect).

Of those not presenting in infancy, most patients with aortic stenosis have no cardiovascular symptoms. Except in the most severe cases, patients do well until the third to fifth decades of life. Some patients have mild exercise intolerance and fatigability. In a small percentage of patients, significant symptoms (eg, chest pain with exercise, dizziness, and syncope) manifest in the first decade. Sudden death is uncommon but may occur in all forms of aortic stenosis with the greatest risk in patients with subvalvular obstruction.

B. Imaging

In most cases the heart is not enlarged. The LV, however, may be slightly prominent. In valvular aortic stenosis, dilation of the ascending aorta is frequently seen.

C. Electrocardiography

Patients with mild aortic stenosis have normal ECGs. Some patients with severe obstruction have LVH and LV strain but even in severe cases, 25% of ECGs are normal. Progressive LVH on serial ECGs indicates a significant obstruction. LV strain is one indication for surgery.

D. Echocardiography

This is a reliable noninvasive technique for the evaluation of all forms of aortic stenosis. Doppler accurately estimates the transvalvular gradient, and the level of obstruction can be confirmed by both two-dimensional echocardiographic images and by the level of flow disturbance revealed by color Doppler.

E. Cardiac Catheterization and Angiocardiography

Left heart catheterization demonstrates the pressure differential between the LV and the aorta and the anatomic level at which the gradient exists. Catheterization is reserved for patients whose resting gradient has reached 60–80 mm Hg and in whom intervention is planned. For those with valvular aortic stenosis, balloon valvuloplasty is usually the first option.
In subvalvular or supravalvular aortic stenosis, interventional catheterization is not effective and surgery is required.

**Treatment**

Percutaneous balloon valvuloplasty is now standard initial treatment for patients with valvular aortic stenosis. Surgery should be considered in symptomatic patients with a high resting gradient (60–80 mm Hg) despite balloon angioplasty, or coexisting aortic insufficiency. In many cases, the gradient cannot be significantly diminished by valvuloplasty without producing aortic insufficiency. Patients who develop significant aortic insufficiency require surgical intervention to repair or replace the valve. The Ross procedure is an alternative to mechanical valve placement in infants and children. In this procedure, the patient’s own pulmonary valve is moved to the aortic position, and an RV-to-pulmonary artery conduit is used to replace the pulmonary valve. Fetal balloon valvuloplasty for critical aortic stenosis is currently being studied to prevent progression of hypoplastic left heart syndrome. Discrete subvalvular aortic stenosis is usually surgically repaired at a lesser gradient because continued trauma to the aortic valve by the subvalvular jet may damage the valve and produce aortic insufficiency. Unfortunately, simple resection is followed by recurrence in more than 25% of patients with subvalvular aortic stenosis. Supravalvar aortic stenosis may also require surgical repair and is commonly associated with William syndrome.

**Course & Prognosis**

All forms of LV outflow tract obstruction tend to be progressive. Pediatric patients with LV outflow tract obstruction—with the exception of those with critical aortic stenosis of infancy—are usually asymptomatic. Symptoms accompanying severe unoperated obstruction (angina, syncope, or HF) are rare but imply serious disease. Children whose obstruction is mild to moderate have normal oxygen consumption and maximum voluntary working capacity. Children in this category with normal resting and exercising (stress) ECGs may safely participate in vigorous physical activity, including nonisometric competitive sports. Children with severe aortic stenosis are predisposed to ventricular dysrhythmias and should refrain from vigorous activity and avoid all isometric exercise.

**3. Mitral Valve Prolapse**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Midsystolic click.
- Late systolic “whooping” or “honking” murmur.
- Typical symptoms include chest pain, palpitations, and dizziness.
- Often overdiagnosed on routine cardiac ultrasound.

**General Considerations**

In this condition as the mitral valve closes during systole, it moves posteriorly or superiorly (prolapses) into the left atrium. Mitral valve prolapse (MVP) occurs in about 2% of thin female adolescents, a minority of whom have concomitant mitral insufficiency. Although MVP is usually an isolated lesion, it can occur in association with connective tissue disorders such as Marfan, Loeys-Dietz, and Ehlers-Danlos syndromes.

**Clinical Findings**

**A. Symptoms and Signs**

Most patients with MVP are asymptomatic. Chest pain, palpitations, and dizziness may be reported, but it is unclear whether these symptoms are more common in affected patients than in the normal population. Chest pain on exertion is rare and should be assessed with cardiopulmonary stress testing. Significant dysrhythmias have been reported, including increased ventricular ectopy and nonsustained ventricular tachycardia. If significant mitral regurgitation is present, atrial arrhythmias may also occur. Standard auscultation technique must be modified to diagnose MVP. A middysystolic click (with or without a systolic murmur) is elicited best in the standing position and is the hallmark of this entity. Conversely, maneuvers that increase LV volume, such as squatting or handgrip exercise, will cause delay or obliteration of the click-murmur complex. The systolic click usually is heard at the apex but may be audible at the left sternal border. A late, short systolic murmur after the click implies mitral insufficiency and is much less common than isolated prolapse. The murmur is not holosystolic, in contrast to rheumatic mitral insufficiency.
**CHAPTER 20**

**B. Imaging**

Most chest radiographs are normal and are not usually indicated in this condition. In the rare case of significant mitral valve insufficiency, the left atrium may be enlarged.

**C. Electrocardiography**

The ECG is usually normal. Diffuse flattening or inversion of T waves may occur in the precordial leads. U waves are sometimes prominent.

**D. Echocardiography**

Echocardiography assesses the degree of myxomatous change of the mitral valve, and the degree of mitral insufficiency. Significant posterior systolic movement of the mitral valve leaflets to the atrial side of the mitral annulus is diagnostic.

**E. Other Testing**

Invasive procedures are rarely indicated. Holter monitoring or event recorders may be useful in establishing the presence of ventricular dysrhythmias in patients with palpitations.

**Treatment & Prognosis**

Propranolol may be effective in treatment of coexisting arrhythmias. Prophylaxis for infectious endocarditis is no longer indicated, based on 2007 AHA guidelines. The natural course of this condition is not well defined. Twenty years of observation indicate that isolated MVP in childhood is usually a benign entity. Surgery for mitral insufficiency is rarely needed.

**4. Other Congenital Left Heart Valvular Lesions**

**A. Congenital Mitral Stenosis**

Congenital mitral stenosis is a rare disorder in which the valve leaflets are thickened and/or fused, producing a diaphragm- or funnel-like structure with a central opening. In many cases, the subvalve apparatus (papillary muscles and chordae) is also abnormal. When mitral stenosis occurs with other left-sided obstructive lesions, such as subaortic stenosis and coarctation of the aorta, the complex is called Shone syndrome. Most patients develop symptoms early in life with tachypnea, dyspnea, and failure to thrive. Physical examination reveals an accentuated S$_2$ and a loud pulmonary closure sound. No opening snap is heard. In most cases, a presystolic crescendo murmur is heard at the apex. Occasionally, only a mid-diastolic murmur can be heard. ECG shows right axis deviation, biatrial enlargement, and RVH. Chest radiograph reveals left atrial enlargement and frequent pulmonary venous congestion. Echocardiography shows abnormal mitral valve structures with reduced leaflet excursion and left atrial enlargement. Cardiac catheterization reveals an elevated pulmonary capillary wedge pressure and pulmonary hypertension, owing to the elevated left atrial pressure.

Mitrail valve repair or mitral valve replacement with a prosthetic mitral valve may be performed, even in young infants, but it is a technically difficult procedure. Mitral valve repair is the preferred surgical option, as valve replacement can have a poor outcome in infants.

**B. Cor Triatriatum**

Cor triatriatum is a rare abnormality in which the pulmonary veins join in a confluence that is not completely incorporated into the left atrium. The pulmonary vein confluence communicates with the left atrium through an opening of variable size, and may be obstructed. Patients may present in a similar way as those with mitral stenosis. Clinical findings depend on the degree of obstruction of pulmonary venous flow into the left atrium. If the communication between the confluence and the left atrium is small and restrictive to flow, symptoms develop early in life. Echocardiography reveals a linear density in the left atrium with a pressure gradient present between the pulmonary venous chamber and the true left atrium. Cardiac catheterization may be needed if the diagnosis is in doubt. High pulmonary wedge pressure and low left atrial pressure (with the catheter passed through the foramen ovale into the true left atrium) support the diagnosis. Angiocardiography identifies the pulmonary vein confluence and the anatomic left atria. Surgical repair is always required in the presence of an obstructive membrane, and long-term results are good. Coexisting mitral valve abnormalities may be noted, including a supravalvular mitral ring or a dysplastic mitral valve.

**DISEASES OF THE AORTA**

Patients at risk for progressive aortic dilation and dissection include those with isolated bicuspid aortic valve, Marfan syndrome, Loeys-Dietz syndrome, Turner syndrome, and type IV Ehlers-Danlos syndrome.

**1. Bicuspid Aortic Valve**

Patients with bicuspid aortic valves have an increased incidence of aortic dilation and dissection, regardless of the
presence of aortic stenosis. Histologic examination demonstrates cystic medial degeneration of the aortic wall, similar to that seen in patients with Marfan syndrome. Patients with an isolated bicuspid aortic valve require regular follow-up even in the absence of aortic insufficiency or aortic stenosis. Significant aortic root dilation requiring surgical intervention typically does not occur until adulthood.

2. Marfan and Loeys-Dietz Syndromes

Marfan syndrome is an autosomal dominant disorder of connective tissue caused by a mutation in the fibrillin-1 gene. Spontaneous mutations account for 25%-30% of cases, and thus family history is not always helpful. Patients are diagnosed by the Ghent criteria and must have at a minimum, major involvement of two body systems plus involvement of a third body system or a positive family history. Body systems involved include cardiovascular, ocular, musculoskeletal, pulmonary, and integumentary. Cardiac manifestations include aortic root dilation and MVP, which may be present at birth. Patients are at risk for aortic dilation and dissection and are restricted from competitive athletics, contact sports, and isometric activities. β-Blockers (eg, atenolol), ACE inhibitors, or angiotensin receptor blockers (eg, losartan) are used to lower blood pressure and slow the rate of aortic dilation. A recent study of atenolol versus losartan in children and young adults with Marfan syndrome showed no difference in the rate of aortic dilation between the two medications. Elective surgical intervention is performed in patients of adult size when the aortic root dimension reaches 50 mm or if there is an increase of greater than 1 cm in root dimension in 1 year. The ratio of actual to expected aortic root dimension is used to determine the need for surgery in the young child. Surgical options include replacement of the dilated aortic root with a composite valve graft (Bentall technique) or a David procedure in which the patient’s own aortic valve is spared and a Dacron tube graft is used to replace the dilated ascending aorta. Young age at diagnosis was previously thought to confer a poor prognosis; however, early diagnosis with close follow-up and early medical therapy has more recently been associated with more favorable outcome. Ventricular dysrhythmias may contribute to the mortality in Marfan syndrome.

Loeys-Dietz syndrome is a connective tissue disorder first described in 2005. Many patients with Loeys-Dietz were thought to have Marfan syndrome in the past. Loeys-Dietz is a result of a mutation in the transforming growth factor β (TGFβ) receptor and is associated with musculoskeletal, skin, and cardiovascular abnormalities. Cardiovascular involvement includes mitral and tricuspid valve prolapse, aneurysms of the PDA, and aortic and pulmonary artery dilation. Dissection and aneurysm formation of arteries throughout the body can occur including in the head and neck vessels.

3. Turner Syndrome

Cardiovascular abnormalities are common in Turner syndrome. Patients are at risk for aortic dissection, typically during adulthood. Risk factors include hypertension regardless of cause, aortic dilation, bicuspid aortic valve, and coarctation of the aorta. There are rare reports of aortic dissection in adult Turner syndrome patients in the absence of any risk factors suggesting that there is a vasculopathic component to this syndrome. Patients with Turner syndrome require routine follow-up from adolescence onward to monitor for this potentially lethal complication.

**CORONARY ARTERY ABNORMALITIES**

Several anomalies involve the origin, course, and distribution of the coronary arteries. Abnormal origin or course of the coronary arteries are often asymptomatic and can go undetected. However, in some instances these children are at risk for sudden death. The most common congenital coronary artery abnormality in infants is anomalous origin of the left coronary artery from the pulmonary artery (ALCAPA) and is discussed in more detail here.

**Anomalous Origin of the Left Coronary Artery from the Pulmonary Artery**

In this condition, the left coronary artery arises from the pulmonary artery rather than the aorta. In neonates, whose pulmonary artery pressure is high, perfusion of the left coronary artery may be inadequate and the infant may be asymptomatic. By age 2 months the pulmonary arterial pressure falls, causing a progressive decrease in myocardial perfusion provided by the anomalous left coronary artery. Ischemia and infarction of the LV is the result. Immediate surgery is indicated to reimplant the left coronary artery and restore myocardial perfusion.

**Clinical Findings**

**A. Symptoms and Signs**

Neonates appear healthy and growth and development are relatively normal until pulmonary artery pressure decreases. Detailed questioning may disclose a history of intermittent abdominal pain (fussiness or irritability), pallor, wheezing, and sweating, especially during or after feeding. Presentation
may be subtle, with nonspecific complaints of “fussiness” or intermittent “colic.” The colic and fussiness are probably attacks of true angina. Presentation may be fulminant at age 2–4 months with sudden, severe HF due to LV dysfunction and mitral insufficiency. On physical examination, the infants are usually well developed and well nourished. The pulses are typically weak but equal. A prominent left precordial bulge is present. A gallop and/or holosystolic murmur of mitral regurgitation is sometimes present, though frequently auscultation alone reveals no obvious abnormalities.

B. Imaging

Chest radiographs show cardiac enlargement, left atrial enlargement, and may show pulmonary venous congestion if left ventricular function has been compromised.

C. Electrocardiography

On the ECG, there is T-wave inversion in leads I and aVL. The precordial leads also show T-wave inversion from V₄–V₇. Deep and wide Q waves are present in leads I, aVL, and sometimes in V₄–V₆. These findings of myocardial infarction are similar to those in adults.

D. Echocardiography

The diagnosis can be made with two-dimensional echo techniques by visualizing a single large right coronary artery arising from the aorta and visualization of the anomalous left coronary artery arising from the main pulmonary artery. Flow reversal in the left coronary (heading toward the pulmonary artery, rather than away from the aorta) confirms the diagnosis. LV dysfunction, echo-bright (ischemic) papillary muscles, and mitral regurgitation are commonly seen.

E. Cardiac Catheterization and Angiocardiography

Angiogram of the aorta fails to show the origin of the left coronary artery. A large right coronary artery fills directly from the aorta, and contrast flows from the right coronary system via collaterals into the left coronary artery and finally into the pulmonary artery. Angiogram of the RV or main pulmonary artery may show the origin of the anomalous vessel. Rarely, a left-to-right shunt may be detected as oxygenated blood passes through the collateral system without delivering oxygen to the myocardium, and passes into the pulmonary artery.

Treatment & Prognosis

The prognosis of ALCAPA depends in part on the clinical appearance of the patient at presentation. Medical management with diuretics and afterload reduction can help stabilize a critically ill patient, but surgical intervention should not be delayed. Surgery involves reimplantation of the anomalous coronary button onto the aorta. The mitral valve may have to be replaced, depending on the degree of injury to the papillary muscles and associated mitral insufficiency. Although a life-threatening problem, cardiac function nearly always recovers if the infant survives the surgery and postoperative period.

CYANOTIC CONGENITAL HEART DISEASE

TETRALOGY OF FALLOT

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Hypoxemic spells during infancy.
- Right-sided aortic arch in 25% of patients.
- Systolic ejection murmur at the upper left sternal border.

General Considerations

In tetralogy of Fallot (ToF), anterior deviation of the infundibular (pulmonary outflow) septum causes narrowing of the right ventricular outflow tract. This deviation also results in a VSD and the aorta then overrides the crest of the ventricular septum. The RV hypertrophies, not because of pulmonary stenosis, but because it is pumping against systemic resistance across a (usually) large VSD. ToF is the most common cyanotic cardiac lesion and accounts for 10% of all congenital heart disease. A right-sided aortic arch is present in 25% of cases, and ASD occurs in 15%.

Obstruction to RV outflow with a large VSD causes a right-to-left shunt at the ventricular level with arterial desaturation. The greater the obstruction and the lower the systemic vascular resistance, the greater is the right-to-left shunt. ToF is associated with deletions in the long arm of chromosome 22 (22q11, DiGeorge syndrome) in as many as 15% of affected children. This is especially common in those with an associated right aortic arch.
Clinical Findings

A. Symptoms and Signs

Clinical findings vary with the degree of RV outflow obstruction. Patients with mild obstruction are minimally cyanotic or acyanotic. Those with severe obstruction are deeply cyanotic from birth. Few children are asymptomatic. In those with significant RV outflow obstruction, many have cyanosis at birth, and nearly all have cyanosis by age 4 months. The cyanosis usually is progressive, as subvalvular obstruction increases. Growth and development are not typically delayed, but easy fatigability and dyspnea on exertion are common. The fingers and toes show variable clubbing depending on age and severity of cyanosis. Historically, older children with ToF would frequently squat to increase systemic vascular resistance. This decreased the amount of right-to-left shunt, forcing blood through the pulmonary circuit, and would help ward off cyanotic spells. Squatting is rarely seen as the diagnosis is now made in infancy.

Hypoxemic spells, also called cyanotic or “Tet spells,” are one of the hallmarks of severe ToF. These spells can occur spontaneously and at any time, but in infants occur most commonly with crying or feeding, while in older children they can occur with exercise. They are characterized by (1) sudden onset of cyanosis or deepening of cyanosis; (2) dyspnea; (3) alterations in consciousness, from irritability to syncope; and (4) decrease or disappearance of the systolic murmur (as RV the outflow tract becomes completely obstructed). These episodes most commonly start at age 4–6 months. Cyanotic spells are treated acutely by administration of oxygen and placing the patient in the knee-chest position (to increase systemic vascular resistance). Intravenous morphine should be administered cautiously, but is helpful for its sedative effect. Propranolol produces β-blockade and may reduce the obstruction across the RV outflow tract through its negative inotropic action. Acidosis, if present, should be corrected with intravenous sodium bicarbonate. Chronic oral prophylaxis of cyanotic spells with propranolol may be useful to delay surgery, but the onset of Tet spells usually prompts surgical intervention. In fact, in the current era, elective surgical repair generally occurs around the age of 3 months so as to avoid the development of Tet spells.

On examination, an RV lift is palpable. $S_2$ is predominantly aortic and single. A grade II–IV/VI, rough, systolic ejection murmur is present at the left sternal border in the third intercostal space and radiates well to the back.

B. Laboratory Findings

Hemoglobin, hematocrit, and red blood cell count are usually elevated in older infants or children secondary to chronic arterial desaturation.

C. Imaging

Chest radiographs show a normal-size heart. The RV is hypertrophied, often shown by an upturning of the apex (boot-shaped heart). The main pulmonary artery segment is usually concave and, if there is a right aortic arch, the aortic knob is to the right of the trachea. The pulmonary vascular markings are usually decreased.

D. Electrocardiography

The QRS axis is rightward, ranging from +90 to +180 degrees. The P waves are usually normal. RVH is always present, but RV strain patterns are rare.

E. Echocardiography

Two-dimensional imaging is diagnostic, revealing thickening of the RV wall, overriding of the aorta, and a large subaortic VSD. Obstruction at the level of the infundibulum and pulmonary valve can be identified, and the size of the proximal pulmonary arteries measured. The anatomy of the coronary arteries should be visualized, as abnormal branches crossing the RV outflow tract are at risk for transection during surgical enlargement of the area.

F. Cardiac Catheterization and Angiocardiography

Cardiac catheterization is generally done mainly in those patients with hypoplastic pulmonary arteries. If a catheterization is done, it reveals a right-to-left shunt at the ventricular level in most cases. Arterial desaturation of varying degrees is present. The RV pressure is at systemic levels and the pressure tracing in the RV is identical to that in the LV if the VSD is large. The pulmonary artery pressure is invariably low. Pressure gradients may be noted at the pulmonary valvular level, the infundibular level, or both. RV angiography reveals RV outflow obstruction and a right-to-left shunt at the ventricular level. The major indications for cardiac catheterization are to establish coronary artery and distal pulmonary artery anatomy if not able to be clearly defined by echocardiography.

Treatment

A. Palliative Treatment

Most centers currently advocate complete repair of ToF during the neonatal or infant period regardless of patient size. However, some centers prefer palliative treatment for small neonates in whom complete correction is deemed risky. Surgical palliation consists of the insertion of a GoreTex shunt from the subclavian artery to the ipsilateral pulmonary artery [modified Blalock-Taussig (BT) shunt] to replace the ductus arteriosus (which is ligated and divided) or stenting of the ductus. This secures a source of pulmonary blood flow regardless of the level of infundibular or valvular obstruction, and some believe, allows for growth of the
patient’s pulmonary arteries (which are usually small) prior to complete surgical correction.

B. Total Correction

Open-heart surgery for repair of ToF is performed at ages ranging from birth to 2 years, depending on the patient’s anatomy and the experience of the surgical center. The current surgical trend is toward earlier repair for symptomatic infants. The major limiting anatomic feature of total correction is the size of the pulmonary arteries. During surgery, the VSD is closed and the obstruction to RV outflow removed. Although a valve sparing procedure is preferred, in many cases a transannular patch is placed across the RV outflow tract as the pulmonary valve is contributing to the obstruction. When a transannular patch repair is done, the patient has PI that is usually well tolerated for years. However, pulmonary valve replacement is eventually necessary once symptoms (usually exercise intolerance) and right ventricular dilation occur. Surgical mortality is low.

Course & Prognosis

Infants with severe ToF are usually deeply cyanotic at birth. These children require early surgery. Complete repair before age 2 years usually produces a good result, and patients are currently living well into adulthood. Depending on the extent of the repair required, patients frequently require additional surgery 10–15 years after their initial repair for replacement of the pulmonary valve. Transcatheter pulmonary valves are now performed in some adolescents and young adults with a history of ToF, avoiding the need for open heart surgery. Patients with ToF are at risk for sudden death due to ventricular dysrhythmias. A competent pulmonary valve without a dilated RV appears to diminish arrhythmias and enhance exercise performance.

PULMONARY ATRESIA WITH VENTRICULAR SEPTAL DEFECT

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Symptoms depend on degree of pulmonary blood flow.
- Pulmonary blood flow via PDA and/or aortopulmonary collaterals.

Complete atresia of the pulmonary valve in association with a VSD is essentially an extreme form of ToF. Because there is no antegrade flow from the RV to the pulmonary artery, pulmonary blood flow must be derived from a PDA or from multiple aortopulmonary collateral arteries (MAPCAs). Symptoms depend on the amount of pulmonary blood flow. If flow is adequate, patients may be stable. If pulmonary flow is inadequate, severe hypoxemia occurs and immediate palliation is required. Newborns are stabilized with intravenous prostaglandin E1 (PGE1) to maintain the PDA while being prepared for surgery. Rarely, if the ductus does not contribute significantly to pulmonary blood flow (eg, the MAPCAs alone are sufficient), PGE1 may be discontinued. Once stabilized, a BT shunt, stenting of the ductus or complete repair is undertaken. The decision to perform palliation or complete repair in a newborn is dependent on surgical expertise and preference in combination with pulmonary artery anatomy. In many centers, a palliative shunt is performed in newborns with severely hypoplastic pulmonary arteries or in those with only MAPCAs as a source of pulmonary blood flow. The goal of the shunt is to augment pulmonary blood flow and encourage vascular growth, and open-heart surgical correction is planned several months later. In children with MAPCAs, relocation of the MAPCAs is performed so that they are connected to the pulmonary artery (unifocalization) to complete the repair.

Echocardiography is usually diagnostic. Cardiac catheterization and angiography or cardiac MRI can confirm the source(s) of pulmonary blood flow and document size of the distal pulmonary arteries.

Pulmonary vascular disease is common in pulmonary atresia with VSD, due both to intrinsic abnormalities of the pulmonary vasculature and to abnormal amounts of pulmonary blood flow. Even patients who have undergone surgical correction as infants are at risk. Pulmonary vascular disease is a common cause of death as early as the third decade of life.

PULMONARY ATRESIA WITH INTACT VENTRICULAR SEPTUM

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Completely different lesion from pulmonary atresia with VSD.
- Cyanosis at birth.
Pulmonary blood flow is always ductal dependent with rare aortopulmonary collateral arteries being present.

RV-dependent coronary arteries sometimes are present.

**General Considerations**

Although pulmonary atresia with intact ventricular septum (PA/IVS) sounds as if it might be related to pulmonary atresia with VSD, it is a distinct cardiac condition. As the name suggests, the pulmonary valve is atretic. The pulmonic annulus usually has a small diaphragm consisting of the fused valve cusps. The ventricular septum is intact. The main pulmonary artery segment is usually present and closely approximated to the atretic valve, but is somewhat hypoplastic. Although the RV is always reduced in size, the degree of reduction is variable. The size of the RV is critical to the success of surgical repair. In some children with PA/IVS, the RV is adequate for an ultimate two-ventricular repair. A normal RV has three component parts (inlet, trabecular or body, and outlet). The absence of any one of the components makes adequate RV function unlikely and a single ventricle palliative approach is necessary. Even with all three components, some RVs are inadequate.

After birth, the pulmonary flow is provided by the ductus arteriosus. MAPCAs are usually not present in this disease, in contrast to pulmonary atresia with VSD. A continuous infusion of PGE1 must be started as soon as possible after birth to maintain ductal patency.

**Clinical Findings**

**A. Symptoms and Signs**

Neonates are usually cyanotic and become more so as the ductus arteriosus closes. A blowing systolic murmur resulting from the associated PDA may be heard at the pulmonary area. A holosystolic murmur is often heard at the lower left sternal border, as many children develop tricuspid insufficiency if the RV is of good size and egress from that ventricle is only through the tricuspid valve. A PFO or ASD is essential for decompression of the right side of the heart.

**B. Imaging**

The heart size varies depending on the degree of tricuspid insufficiency. With severe tricuspid insufficiency, right atrial enlargement may be massive and the cardiac silhouette may fill the chest on radiograph. In patients with an associated hypoplastic tricuspid valve and or RV, most of the systemic venous return travels right-to-left across the ASD and so the heart size can be normal.

**C. Electrocardiography**

ECG reveals a left axis for age (45–90 degrees) in the frontal plane. Left ventricular forces dominate the ECG, and there is a paucity of RV forces, particularly with a hypoplastic RV. Findings of right atrial enlargement are usually striking.

**D. Echocardiography**

Echocardiography shows atresia of the pulmonary valve with varying degrees of RV cavity and tricuspid annulus hypoplasia. Patency of an intra-atrial communication and ductus are verified by echocardiography.

**E. Cardiac Catheterization and Angiocardiography**

RV pressure is often suprasystemic. Angiogram of the RV reveals no filling of the pulmonary artery. Unrestricted flow through the ASD is a necessity, since egress of blood from the right heart can only occur across the atrial defect and into the left atrium. A Rashkind balloon atrial septostomy may be required to open any inadequate existing communication across the atrial septum. Some children with pulmonary atresia and an intact ventricular septum have sinusoids between the RV and the coronary arteries. Even with all three components, some RVs are inadequate.

After birth, the pulmonary flow is provided by the ductus arteriosus. MAPCAs are usually not present in this disease, in contrast to pulmonary atresia with VSD. A continuous infusion of PGE1 must be started as soon as possible after birth to maintain ductal patency.

**Treatment & Prognosis**

As in all ductal-dependent lesions, PGE1 is used to stabilize the patient and maintain patency of the ductus until surgery can be performed. Surgery is usually undertaken in the first week of life. If the RV is hypoplastic, significant sinusoids are present, there is RV-dependent coronary circulation (lack of antegrade filling of the coronaries from the aorta), or the pulmonic valve cannot be opened successfully during cardiac catheterization, a BT shunt or ductal stenting is performed to establish pulmonary blood flow. Later in infancy, a communication between the RV and pulmonary artery can be created to stimulate RV cavity growth. If either RV dimension or function is inadequate for two-ventricular repair, an approach similar to that taken for a single ventricle pathway best serves these children (see section on Hypoplastic Left Heart Syndrome). Children with significant
TRICUSPID ATRESIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► Marked cyanosis present from birth.
► ECG with left axis deviation, right atrial enlargement, and LVH.

General Considerations

In tricuspid atresia, there is complete atresia of the tricuspid valve with no direct communication between the right atrium and the RV. There are two types of tricuspid atresia based on the relationship of the great arteries (normally related or transposed great arteries). The entire systemic venous return must flow through the atrial septum (either ASD or PFO) to reach the left atrium. The left atrium thus receives both the systemic venous return and the pulmonary venous return. Complete mixing occurs in the left atrium, resulting in variable degrees of arterial desaturation.

Because there is no flow to the RV, development of the RV depends on the presence of a ventricular left-to-right shunt. Severe hypoplasia of the RV occurs when there is no VSD or when the VSD is small.

Clinical Findings

A. Symptoms and Signs

Symptoms usually develop in early infancy with cyanosis present at birth in most infants. Growth and development are poor, and the infant usually exhibits exhaustion during feedings, tachypnea, and dyspnea. Patients with increased pulmonary blood flow may develop HF with less prominent cyanosis. The degree of pulmonary blood flow is most dependent on pulmonary vascular resistance. Those patients with low pulmonary vascular resistance will have increased pulmonary blood flow. A murmur from the VSD is usually present and heard best at the lower left sternal border. Digital clubbing is present in older children with long-standing cyanosis.

B. Imaging

The heart is slightly to markedly enlarged. The main pulmonary artery segment is usually small or absent. The size of the right atrium is moderately to massively enlarged, depending on the size of the communication at the atrial level. The pulmonary vascular markings are usually decreased. Pulmonary vascular markings may be increased if pulmonary blood flow is not restricted by the VSD or pulmonary stenosis.

C. Electrocardiography

The ECG shows marked left axis deviation. The P waves are tall and peaked, indicative of right atrial hypertrophy. LVH or LV dominance is found in almost all cases. RV forces on the ECG are usually low or absent.

D. Echocardiography

Two-dimensional echocardiography is diagnostic and show absence of the tricuspid valve, the relationship between the great arteries, the anatomy of the VSD, presence of an ASD or PFO, and the size of the pulmonary arteries. Color-flow Doppler imaging can help identify atrial level shunting and levels of restriction of pulmonary blood flow, either at the VSD or in the RV outflow tract.

E. Cardiac Catheterization and Angiocardiography

Catheterization reveals a right-to-left shunt at the atrial level. Because of mixing in the left atrium, oxygen saturations in the LV, RV, pulmonary artery, and aorta are identical to those in the left atrium. Right atrial pressure is increased if the ASD is restrictive. LV and systemic pressures are normal. The catheter cannot be passed through the tricuspid valve from the right atrium to the RV. A balloon atrial septostomy is performed if a restrictive PFO or ASD is present.

Treatment & Prognosis

In infants with unrestricted pulmonary blood flow, conventional anticongestive therapy with diuretics and afterload reduction should be given until the infant begins to outgrow the VSD. Sometimes, a pulmonary artery band is needed to protect the pulmonary bed from excessive flow and development of pulmonary vascular disease.
Staged palliation of tricuspid atresia is the usual surgical approach. In infants with diminished pulmonary blood flow, PGE1 is given until an aortopulmonary shunt (BT shunt or ductal stent) can be performed. A Glenn procedure (superior vena cava to pulmonary artery anastomosis) is done with takedown of the aortopulmonary/BT shunt at 4–6 months when saturations begin to fall, and completion of the Fontan procedure (redirection of inferior vena cava and superior vena cava to pulmonary artery) is performed when the child reaches around 15 kg.

The long-term prognosis for children treated by the Fontan procedure is unknown, although patients now are living into their late 20s and early 30s. In the short term, the best results for the Fontan procedure occur in children with low pulmonary artery pressures prior to open-heart surgery.

### HYPOPLASTIC LEFT HEART SYNDROME

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- **Mild cyanosis at birth.**
- **Minimal auscultatory findings.**
- **Rapid onset of shock with ductal closure.**

**General Considerations**

Hypoplastic left heart syndrome (HLHS) includes several conditions in which obstructive lesions of the left heart are associated with hypoplasia of the LV. The syndrome occurs in 1.4%–3.8% of infants with congenital heart disease.

Stenosis or atresia of the mitral and aortic valves is the rule. In the neonate, survival depends on a PDA because ante-grade flow into the systemic circulation is inadequate or nonexistent. The PDA provides the only flow to the aorta and coronary arteries. Children with HLHS are usually stable at birth, but they deteriorate rapidly as the ductus closes in the first week of life. Untreated, the average age at death is the first week of life. Rarely, the ductus remains patent and infants may survive for weeks to months without PGE1 therapy.

The diagnosis is often made prenatally by fetal echocardiography. Prenatal diagnosis aids in counseling for the expectant parents and planning for the delivery of the infant at or near a center with experience in treating HLHS.

**Clinical Findings**

**A. Symptoms and Signs**

Neonates with HLHS appear stable at birth because the ductus is patent. They deteriorate rapidly as the ductus closes, with shock and acidosis secondary to inadequate systemic perfusion. Oxygen saturation may actually increase for a period of time as the ductus closes due to increased blood flowing to the lungs.

**B. Imaging**

Chest radiograph in the first day of life may be relatively unremarkable, with the exception of a small cardiac silhouette. Later, chest radiographs demonstrate cardiac enlargement with severe pulmonary venous congestion if the PDA has begun closing or if the baby has been placed on supplemental oxygen increasing pulmonary blood flow.

**C. Electrocardiography**

The ECG shows right axis deviation, right atrial enlargement, and RVH with a relative paucity of LV forces. The small Q wave in lead V6 may be absent, and a qR pattern is often seen in lead V1.

**D. Echocardiography**

Echocardiography is diagnostic. A hypoplastic aorta and LV with atretic or severely stenotic mitral and aortic valves are diagnostic. The systemic circulation is dependent on the PDA. Color-flow Doppler imaging shows retrograde flow in the ascending aorta, as the coronary arteries are supplied by the ductus via the small native aorta.

**Treatment & Prognosis**

Initiation of PGE1 is essential and lifesaving, as systemic circulation depends on a patent ductus arteriosus. Later management depends on balancing pulmonary and systemic blood flow both of which depend on the RV. At a few days of age the pulmonary resistance falls, favoring pulmonary over-circulation and systemic underperfusion. Therapy is then directed at encouraging systemic blood flow. Despite hypoxia and cyanosis, supplemental oxygen is avoided as this will decrease pulmonary resistance and lead to further increases in pulmonary blood flow. In some centers, nitrogen is used to decrease inspired oxygen to as low as 17%. This therapy must be carefully monitored, but results in increased pulmonary arterial resistance, which encourages systemic blood flow and improves systemic perfusion. Systemic afterload reduction will also increase systemic perfusion. Adequate perfusion can usually be obtained by keeping systemic O2 saturation between 65% and 80%, or more accurately a PO2 of 40 mm Hg.
Staged surgical palliation is the most common management approach. In the Norwood procedure, the relatively normal main pulmonary artery is transected and connected to the small ascending aorta. The entire aortic arch must be reconstructed due to its small size. Then, either a BT shunt (from the subclavian artery to the pulmonary artery) or a Sano shunt (from the RV to the pulmonary artery) must be created to restore pulmonary blood flow. Children who have a Norwood procedure will later require a Glenn anastomosis (superior vena cava to pulmonary artery with takedown of the systemic-pulmonary shunt) and then a Fontan (inferior vena cava to pulmonary artery, completing the systemic venous bypass of the heart) at ages 6 months and 2–3 years, respectively. Despite advances in surgical technique and postoperative care, HLHS remains one of the most challenging lesions in pediatric cardiology, with 1-year survival as low as 70%.

Orthotopic heart transplantation is also a treatment option for newborns with HLHS, but in the current era is typically only performed in infants who are considered poor Norwood candidates. Heart transplantation is more commonly utilized in the event of a failed surgical palliation or if the systemic RV fails (often in adolescence or young adulthood).

Recently, some centers offer a “hybrid” approach to HLHS as a result of collaboration between surgeons and interventional cardiologists. In the hybrid procedure, the chest is opened surgically and the branch pulmonary arteries are banded, to limit pulmonary blood flow. Then, also through the open chest, a PDA stent is placed by the interventionalist to maintain systemic output. The second stage is considered a “comprehensive Glenn,” in which the pulmonary artery bands and ductal stent are taken down, the aortic arch is reconstructed and the superior vena cava is surgically connected to the pulmonary arteries. Short-term (30 day) survival after the first-stage “hybrid” is greater than 90% at the most experienced centers, but second stage risks and complications mitigate some of that initial survival advantage. Long-term follow-up data are not yet available.

D. Echocardiography

Two-dimensional imaging and Doppler evaluation demonstrate the anatomy and physiology well. The aorta arises from the RV and the pulmonary artery arises from the LV. Associated defects, such as a VSD, RV, or LV outflow tract obstruction, or coarctation, must be evaluated. The atrial septum should be closely examined, as any restriction could prove detrimental as the child awaits repair. The coronary anatomy is variable and must be defined prior to surgery.

E. Cardiac Catheterization and Angiography

A Rashkind balloon atrial septostomy is frequently performed in complete transposition if the interatrial communication is restrictive. This procedure can be done at the bedside with echocardiographic guidance in most cases. The coronary anatomy can be delineated by ascending aortography if not well seen by echocardiography.

Treatment

Early corrective surgery is recommended. The arterial switch operation (ASO) has replaced the previously performed atrial switch procedures (Mustard and Senning operations). The ASO is performed at age 4–7 days. The arteries are transected above the level of the valves and switched, while the coronaries are separately reimplanted. Small associated VSDs may be left to close on their own, but large VSDs are repaired. The ASD is also closed. Early surgical repair (< 14 days of age) is vital for patients with TGA and an intact ventricular septum to avoid potential deconditioning of the LV as it pumps to the low-resistance pulmonary circulation. If a large, unrestricted VSD is present, LV pressure is maintained at systemic levels, the LV does not become deconditioned, and corrective surgery can be delayed for a few months. Surgery should be performed by age 3–4 months in those with TGA and a VSD because of the high risk of early pulmonary vascular disease associated with this defect.

Operative survival after the ASO is greater than 95% in major centers. The main advantage of the arterial switch procedure in comparison to the atrial switch procedures (Mustard and Senning operations) is that the systemic ventricle is the LV. Patients who have undergone an atrial switch undergo surgical patch placement to baffle the venous return through the atria to the opposite ventricle. They then have an RV as their systemic ventricle, leaving them with significant late risk of RV failure and need for heart transplantation and are at risk for atrial baffle obstruction.

1. Congenitally Corrected Transposition of the Great Arteries

Congenitally corrected transposition of the great arteries (cTGA) is a relatively uncommon congenital heart disease. Patients may present with cyanosis, heart failure, or be asymptomatic, depending on the associated lesions. In cTGA, both atrioventricular and ventriculoarterial discordance occurs so that the right atrium connects to a morphologic LV, which supports the pulmonary artery. Conversely, the left atrium empties via a tricuspid valve into a morphologic RV, which supports the aorta. Common associated lesions are VSD and pulmonary stenosis. A dysplastic left-sided tricuspid valve is almost always present. In the absence of associated lesions, patients with cTGA are often undiagnosed until adulthood when they present with left-sided AV valve insufficiency or arrhythmias.

Previously, surgical repair was directed at VSD closure and relief of pulmonary outflow tract obstruction—a technique that maintained the RV as the systemic ventricle with outflow to the aorta. It is now recognized that these patients have a reduced life span due to systemic RV failure; thus other surgical techniques have been advocated. The double-switch procedure is one such technique. An atrial level switch (Mustard or Senning technique) is performed, in which pulmonary and systemic venous blood are baffled such that they drain into the contralateral ventricle (systemic venous return drains into the RV and pulmonary venous return drains into the LV). An ASO then restores the morphologic LV to its position as systemic ventricle.

Patients with cTGA have an increased incidence of complete heart block with an estimated risk of 1% per year and an overall frequency of 50%.

2. Double-Outlet Right Ventricle

In this uncommon malformation, both great arteries arise from the RV. There is always a VSD that allows blood to exit
the LV. Presenting symptoms depend on the relationship of the VSD to the semilunar valves. The VSD can be in variable positions, and the great arteries could be normally related or malposed. In the absence of outflow obstruction, a large left-to-right shunt exists and the clinical picture resembles that of a large VSD. Pulmonary stenosis may be present, particularly if the VSD is remote from the pulmonary artery. This physiology is similar to ToF. Alternatively, if the VSD is nearer the pulmonary artery, aortic outflow may be obstructed (called the Taussig-Bing malformation). Early primary correction is the goal. LV flow is directed to the aorta across the VSD (closing the VSD), and an RV to pulmonary artery conduit is placed to maintain unobstructed flow through the pulmonary circulation. If the aorta is far from the VSD, an arterial switch may be necessary. Echocardiography is usually sufficient to make the diagnosis and determine the orientation of the great vessels and their relationship to the VSD.

The malformation is classified as either intra-, supra-, or infracardiac. Infracardiac TAPVR occurs when the pulmonary venous confluence drains directly into the heart, usually via the coronary sinus into the right atrium (rarely direct drainage into the right atrium). Supracardiac (or supradiaphragmatic) return is defined as a confluence that drains into the right superior vena cava, innominate vein, or persistent left superior vena cava. In infracardiac (or infradiaphragmatic) return, the confluence drains below the diaphragm usually into the portal venous system which empties into the inferior vena cava. Infracardiac pulmonary venous return is very frequently obstructed. This obstruction to pulmonary venous drainage makes this lesion a potential surgical emergency. Supracardiac veins may also be obstructed, though less commonly. Rarely, the pulmonary venous confluence drains to more than one location, called mixed TAPVR.

Because the entire venous drainage from the body returns to the right atrium, a right-to-left shunt must be present at the atrial level, either as an ASD or a PFO. Occasionally, the atrial septum is restrictive and balloon septostomy is needed at birth to allow filling of the left heart.

### Clinical Findings

**A. Unobstructed Pulmonary Venous Return**

Patients with unobstructed TAPVR and a large atrial communication tend to have high pulmonary blood flow and typically present with cardiomegaly and HF rather than cyanosis. Oxygen saturations in the high 80s or low 90s are common. Most patients in this group have mild to moderate elevation of pulmonary artery pressure owing to elevated pulmonary blood flow. In most instances, pulmonary artery pressure does not reach systemic levels.

1. **Symptoms and signs**—Patients may have mild cyanosis and tachypnea in the neonatal period and early infancy. Examination discloses dusky nail beds and mucous membranes, but overt cyanosis and digital clubbing are usually absent. An RV heave is palpable, and P₂ is increased. A systolic and diastolic murmur may be heard as a result of increased flow across the pulmonary and tricuspid valves, respectively.

2. **Imaging**—Chest radiography reveals cardiomegaly involving the right heart and pulmonary artery. Pulmonary vascular markings are increased.

3. **Electrocardiography**—ECG shows right axis deviation and varying degrees of right atrial enlargement and right ventricular hypertrophy. A qR pattern is often seen over the right precordial leads.

4. **Echocardiography**—Demonstration by echocardiography of a discrete chamber posterior to the left atrium and an obligatory right-to-left atrial level shunt is strongly suggestive of the diagnosis. The availability of two-dimensional echocardiography plus color-flow Doppler has increased

---

**TYPICAL FEATURES**

- Abnormal pulmonary venous connection leading to cyanosis.
- Occurs with or without a murmur and may have accentuated P₂.
- Right atrial enlargement and RVH.
diagnostic accuracy such that diagnostic cardiac catheterization is rarely required.

B. With Obstructed Pulmonary Venous Return

This group includes many patients with infracardiac TAPVR and a few of the patients in whom venous drainage is into a systemic vein above the diaphragm. The pulmonary venous return is usually obstructed at the level of the ascending or descending vein that connects the confluence to the systemic veins to which it is draining. Obstruction can be caused from extravascular structures (such as the diaphragm), or by inherent stenosis within the ascending or descending vein.

1. Symptoms and signs—Infants usually present shortly after birth with severe cyanosis and respiratory distress and require early corrective surgery. Cardiac examination discloses a striking RV impulse. S₂ is markedly accentuated and single. Although there is often no murmur, sometimes, a systolic murmur is heard over the pulmonary area with radiation over the lung fields. Diastolic murmurs are uncommon.

2. Imaging—The heart is usually small and pulmonary venous congestion severe with associated air bronchograms. The chest radiographic appearance may lead to an erroneous diagnosis of severe lung disease. In less severe cases, the heart size may be normal or slightly enlarged with mild pulmonary venous congestion.

3. Electrocardiography—The ECG shows right axis deviation, right atrial enlargement, and RVH.

4. Echocardiography—Echocardiography shows a small left atrium and LV, a dilated right heart with high RV pressure. For infracardiac TAPVR, appearance of a vessel lying parallel and anterior to the descending aorta and to the left of the inferior vena cava may represent the vein draining the confluence caudally toward the diaphragm. Color-flow Doppler echocardiography will demonstrate a right-to-left atrial level shunt and may reveal flow disturbance, commonly near the confluence or in the liver, where flow is obstructed.

5. Cardiac catheterization and angiography—If echocardiography does not confirm the anatomy, cardiac catheterization and angiography demonstrate the site of entry of the anomalous veins, determine the degree of pulmonary hypertension, and calculate pulmonary vascular resistance.

Treatment

Surgery is always required for TAPVR. If pulmonary venous return is obstructed, surgery must be performed immediately (obstructed TAPVR represents one of the few surgical emergencies in congenital heart disease). If early surgery is not required and the atrial septum is restrictive, a balloon atrial septostomy can be performed in newborns, to be followed shortly by less emergent surgical repair.

Course & Prognosis

Most children with TAPVR do well after surgery. However, some surgical survivors develop late stenosis of the pulmonary veins. Pulmonary vein stenosis is an intractable condition that is difficult to treat either with interventional catheterization or surgery and has a poor prognosis. A heart-lung transplant may be the only remaining option available to those with severe pulmonary vein stenosis. By avoiding direct suturing at the pulmonary venous ostia, the chance of recurrent stenosis at the anastomotic site is lessened. Unfortunately, any manipulation of the pulmonary veins increases the risk of stenosis.

TRUNCUS ARTERIOSUS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

» Early HF with or without cyanosis.
» Systolic ejection click.

General Considerations

Truncus arteriosus accounts for less than 1% of congenital heart malformations. A single great artery arises from the heart, giving rise to the systemic, pulmonary, and coronary circulations. Truncus develops embryologically as a result of failure of the division of the common truncus arteriosus into the aorta and the pulmonary artery. A VSD is almost always present. The number of truncal valve leaflets varies from one to six, and the valve may be insufficient or stenotic.

Truncus arteriosus is divided into subtypes by the anatomy of the pulmonary circulation. A single main pulmonary artery may arise from the base of the trunk and gives rise to branch pulmonary arteries (type 1). Alternatively, the pulmonary arteries may arise separately from the common trunk, either in close association with one another (type 2) or widely separated (type 3). This lesion can occur in association with an interrupted aortic arch.

In patients with truncus, blood from both ventricles leaves the heart through a single exit. Thus, oxygen saturation in
the pulmonary artery is equal to that in the systemic arteries. The degree of systemic arterial oxygen saturation depends on the ratio of pulmonary to systemic blood flow. If pulmonary vascular resistance is normal, the pulmonary blood flow is greater than the systemic blood flow and the saturation is relatively high. If pulmonary vascular resistance is elevated because of pulmonary vascular obstructive disease or small pulmonary arteries, pulmonary blood flow is reduced and oxygen saturation is low. The systolic pressures are systemic in both ventricles.

**Clinical Findings**

**A. Symptoms and Signs**

High pulmonary blood flow characterizes most patients with truncus arteriosus. These patients are usually minimally cyanotic and present in HF. Examination of the heart reveals a hyperactive precordium. A systolic thrill is common at the lower left sternal border. A loud early systolic ejection click is commonly heard. S₂ is single and accentuated. A loud holosystolic murmur is audible at the left lower sternal border. A diastolic flow murmur can often be heard at the apex due to increased pulmonary venous return crossing the mitral valve. An additional diastolic murmur of truncal insufficiency may be present.

Patients with decreased pulmonary blood flow are more profoundly cyanotic early. The most common manifestations are growth retardation, easy fatigability, and HF. The heart is not hyperactive. S₁ and S₂ are single and loud. A systolic murmur is heard at the lower left sternal border. No mitral flow murmur is heard, as pulmonary venous return is decreased. A loud systolic ejection click is commonly heard. In the current era, this lesion is often diagnosed by prenatal screening echocardiography.

**B. Imaging**

The common radiographic findings are cardiomegaly, absence of the main pulmonary artery segment, and a large aorta that has a right arch 30% of the time. The pulmonary vascular markings vary with the degree of pulmonary blood flow.

**C. Electrocardiography**

The axis is usually normal. RVH or combined ventricular hypertrophy is commonly present.

**D. Echocardiography**

Images generally show override of a single great artery (similar to ToF, but no second great artery arises directly from the heart). The origin of the pulmonary arteries and the degree of truncal valve abnormality can be defined. Color-flow Doppler can aid in the description of pulmonary flow and the function of the truncal valve, both of which are critical to management. Echocardiography is critical in identifying associated lesions which will impact surgical planning, such as the presence of an interrupted aortic arch.

**E. Angiocardiography**

Cardiac catheterization is not routinely performed but may be of value in older infants in whom pulmonary vascular disease must be ruled out. The single most important angiogram would be from the truncal root, as both the origin of the pulmonary arteries and the amount of truncal insufficiency would be seen from one injection.

**Course & Prognosis**

Children with a good surgical result generally do well. Outcome is also dependent to some degree on anatomy and integrity of the truncal valve, which becomes the “neoaortic” valve. Patients with a dysplastic valve may eventually require surgical repair or replacement of this valve. In addition, similar to patients with ToF, they eventually outgrow the RV-to-pulmonary artery conduit placed in infancy and require revision of the conduit in later childhood. The risk of early pulmonary vascular obstructive disease is high in the unrepaired patient and a decision to delay open-heart surgery beyond age 4–6 months is not wise even in stable patients.

**QUALITY IMPROVEMENT IN CONGENITAL HEART DISEASE**

The National Pediatric Cardiology Quality Improvement Collaborative (NPC-QIC) was formed in response to the Joint Council on Congenital Heart Disease (JCCHD) initiative to improve outcomes of children with heart disease. The mission of the NPC-QIC is to build a collaborative network of pediatric cardiologists and an associated database to serve as the foundation for improvement projects such as
improving survival and quality of life in infants with HLHS. As outcomes improve and children with complex congenital heart disease are surviving into adulthood, subspecialty clinics addressing the needs of adults with repaired or palliated congenital heart disease are required to assess and advise patients regarding adult issues such as impact of pregnancy, risks of anticoagulation during pregnancy, and appropriate adult career choices.

ACQUIRED HEART DISEASE

RHEUMATIC FEVER

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► Preceding Group A streptococcal infection.
► Diagnosis: initial acute rheumatic fever: two major manifestations or one major plus two minor manifestations.
► Diagnosis: recurrent acute rheumatic fever: two major or one major and two minor or three minor manifestations.
► Major criteria
  • Carditis
  • Arthritis
  • Chorea
  • Erythema marginatum
  • Subcutaneous nodules
► Minor criteria
  • Polyarthralgia or monoarthralgia
  • Fever ($\geq 38.5^\circ$C)
  • Elevated inflammatory markers
  • Prolonged PR interval on electrocardiogram

Rheumatic fever remains a major cause of morbidity and mortality in developing countries that suffer from poverty, overcrowding, and poor access to health care. Even in developed countries, rheumatic fever has not been entirely eradicated. The overall incidence in the United States is less than 1 per 100,000. Group A $\beta$-hemolytic streptococcal infection of the upper respiratory tract is the essential trigger in predisposed individuals. Only certain serotypes of group A Streptococcus cause rheumatic fever. The latest attempts to define host susceptibility implicate immune response genes that are present in approximately 15% of the population. The immune response triggered by infection of the pharynx with group A streptococci consists of (1) sensitization of B lymphocytes by streptococcal antigens, (2) formation of anti-streptococcal antibody, (3) formation of immune complexes that cross-react with cardiac sarcolemma antigens, and (4) myocardial and valvular inflammatory response.

The peak age of risk in the United States is 5–15 years. The disease is slightly more common in girls and in African Americans. The annual death rate from rheumatic heart disease in school-aged children (whites and non-whites) recorded in the 1980s was less than 1 per 100,000.

Clinical Findings

Two major or one major and two minor manifestations (plus supporting evidence of streptococcal infection) based on the modified Jones criteria are needed for the diagnosis of acute rheumatic fever (Table 20–13). Except in cases of rheumatic fever manifesting solely as Sydenham chorea or long-standing carditis, there should be clear evidence of a streptococcal infection such as scarlet fever, a positive throat culture for group A $\beta$-hemolytic Streptococcus, and increased antistreptolysin O or other streptococcal antibody titers.

The antistreptolysin O titer is significantly higher in rheumatic fever than in uncomplicated streptococcal infections.

**A. Carditis**

Carditis is the most serious consequence of rheumatic fever and varies from minimal to life-threatening HF. The term *carditis* implies pancardiac inflammation, but it may be limited to valves, myocardium, or pericardium. Valvulitis is frequently seen, with the mitral valve most commonly affected. Mitral insufficiency is the most common valvular residua of acute rheumatic carditis. Mitral stenosis after acute rheumatic fever is rarely encountered until 5–10 years after the first episode. Thus, mitral stenosis is much more commonly seen in adults than in children.

An early decrescendo diastolic murmur consistent with aortic insufficiency is occasionally encountered as the sole valvular manifestation of rheumatic carditis. The aortic valve is the second most common valve affected in polyvalvular as well as in single-valve disease. The aortic valve is involved more often in males and in African Americans. Dominant aortic stenosis of rheumatic origin does not occur in pediatric patients. In one large study, the shortest length of time observed for a patient to develop dominant aortic stenosis secondary to rheumatic heart disease was 20 years.

**B. Polyarthritis**

The large joints (knees, hips, wrists, elbows, and shoulders) are most commonly involved and the arthritis is typically migratory. Joint swelling and associated limitation of movement should be present. This is one of the more common major criteria, occurring in 80% of patients. Arthralgia alone is not a major criterion.

**C. Sydenham Chorea**

Sydenham chorea is characterized by involuntary and purposeless movements and is often associated with emotional lability. These symptoms become progressively worse and may be accompanied by ataxia and slurring of speech. Muscular weakness becomes apparent following the onset of the involuntary movements. Chorea is self-limiting, although it may last up to 3 months. Chorea may not be apparent for months to years after the acute episode of rheumatic fever.

**D. Erythema Marginatum**

A macular, serpiginous, erythematous rash with a sharply demarcated border appears primarily on the trunk and the extremities. The face is usually spared.

**E. Subcutaneous Nodules**

These usually occur only in severe cases, and then most commonly over the joints, scalp, and spinal column. The nodules vary from a few millimeters to 2 cm in diameter and are nontender and freely movable under the skin.

**Treatment & Prophylaxis**

**A. Treatment of the Acute Episode**

1. **Anti-infective therapy**—Eradication of the streptococcal infection is essential. Long-acting benzathine penicillin is the drug of choice. Depending on the age and weight of the patient, a single intramuscular injection of 0.6–1.2 million units is effective; alternatively, give penicillin V, 250–500 mg orally 2–3 times a day for 10 days, or amoxicillin, 50 mg/kg (maximum 1 g) once daily for 10 days. Narrow-spectrum cephalosporins, clindamycin, azithromycin, or clarithromycin are used in those allergic to penicillin.

2. **Anti-inflammatory agents**

   a. **Aspirin**—Aspirin, 30–60 mg/kg/day, is given in four divided doses. This dose is usually sufficient to affect dramatic relief of arthritis and fever. Higher dosages carry a greater risk of side effects and there are no proven short- or long-term benefits of high doses that produce salicylate blood levels of 20–30 mg/dL. The duration of therapy is tailored to meet the needs of the patient, but 2–6 weeks of therapy with reduction in dose toward the end of the course is usually sufficient. Other nonsteroidal anti-inflammatory agents used because of concerns about Reye syndrome are less effective than aspirin.

   b. **Corticosteroids**—There is no clear evidence to support the use of corticosteroids, but they are occasionally used for those with severe carditis.

3. **Therapy in heart failure**—Treatment for HF is based on symptoms and severity of valve involvement and cardiac dysfunction (see section on Heart Failure, earlier).

4. **Bed rest and ambulation**—Bed rest is not required in most cases. Activity level should be commensurate with symptoms and children should be allowed to self-limit their activity level while affected. Most acute episodes of rheumatic fever are managed on an outpatient basis.

**B. Treatment After the Acute Episode**

1. **Prevention**—Prevention is critical, as patients who have had rheumatic fever are at greater risk of recurrence if future group A β-hemolytic streptococcal infections are inadequately treated. Follow-up visits are essential to reinforce the necessity for prophylaxis, with regular intramuscular long-acting benzathine penicillin injections preferred to oral medication due to better adherence. Long-term (possibly lifelong) prophylaxis is recommended for patients with residual rheumatic heart disease. More commonly, with no or transient cardiac involvement, 5–10 years of therapy or discontinuance in early adulthood (age 21) (whichever is longer) is an effective approach.
The following preventive regimens are in current use:

A. **Penicillin G benzathine**—600,000 units for less than 27 kg, 1.2 million units for more than 27 kg intramuscularly every 4 weeks is the drug of choice.

B. **Penicillin V**—250 mg orally twice daily is much less effective than intramuscular penicillin benzathine G (5.5 vs 0.4 streptococcal infections per 100 patient-years).

C. **Sulfadiazine**—500 mg for less than 27 kg and 1 g for more than 27 kg, once daily. Blood dyscrasias and lesser effectiveness in reducing streptococcal infections make this drug less satisfactory than penicillin benzathine G. This is the recommended regimen for penicillin-allergic patients.

D. **Erythromycin**—250 mg orally twice a day may be given to patients who are allergic to both penicillin and sulfonamides. Azithromycin or clarithromycin may also be used.

2. **Residual valvular damage**—As described above, the mitral and aortic valves are most commonly affected by rheumatic fever and the severity of carditis is quite variable. In the most severe cases, cardiac failure or the need for a valve replacement can occur in the acute setting. In less severe cases, valve abnormalities can persist, requiring lifelong medical management and eventual valve replacement. Other patients fully recover without residual cardiac sequelae.

Although antibiotic prophylaxis to protect against endocarditis used to be recommended for those with residual valvular abnormalities, the criteria for prevention of IE were revised in 2007 and routine prophylaxis is recommended only if a prosthetic valve is in place.

Kawasaki disease was first described in Japan in 1967 and was initially called mucocutaneous lymph node syndrome. The cause is unclear and there is no specific diagnostic test. Kawasaki disease is the leading cause of acquired heart disease in children in the United States. Eighty percent of patients are younger than 5 years old (median age at diagnosis is 2 years), and the male-to-female ratio is 1.5:1. Diagnostic criteria are fever for more than 5 days and at least four of the following features: (1) bilateral, painless, nonexudative conjunctivitis; (2) lip or oral cavity changes (eg, lip cracking and fissuring, strawberry tongue, and inflammation of the oral mucosa); (3) cervical lymphadenopathy greater than or equal to 1.5 cm in diameter and usually unilateral; (4) polymorphous exanthema; and (5) extremity changes (redness and swelling of the hands and feet with subsequent desquamation). Clinical features not part of the diagnostic criteria, but frequently associated with Kawasaki disease, are shown in Table 20–14.

The potential for cardiovascular complications is the most serious aspect of Kawasaki disease. Complications during the acute illness include myocarditis, pericarditis, valvular heart disease (usually mitral or aortic regurgitation), and coronary arteritis. Patients with fever for at least 5 days but fewer than four of the diagnostic features can be diagnosed with incomplete Kawasaki disease, especially if

they have coronary artery abnormalities detected by echocardiography. Comprehensive recommendations regarding the evaluation for children with suspected incomplete Kawasaki disease were outlined in a 2004 Statement by the American Heart Association (see references at the end of this section).

Coronary artery lesions range from mild transient dilation of a coronary artery to large aneurysms. Aneurysms rarely form before day 10 of illness. Untreated patients have a 15%–25% risk of developing coronary aneurysms. Those at greatest risk for aneurysm formation are males, young infants (< 6 months), and those not treated with intravenous immunoglobulin (IVIG). Most coronary artery aneurysms resolve within 5 years of diagnosis; however, as aneurysms resolve, associated obstruction or stenosis (19% of all aneurysms) may develop, which may result in coronary ischemia. Giant aneurysms (> 8 mm) are less likely to resolve, and nearly 50% eventually become stenotic. Of additional concern, acute thrombosis of an aneurysm can occur, resulting in myocardial infarction that is fatal in approximately 20% of cases.

**Treatment**

Immediate management of Kawasaki disease includes IVIG and high-dose aspirin. This therapy is effective in decreasing the incidence of coronary artery dilation and aneurysm formation. The currently recommended regimen is 2 g/kg of IVIG administered over 10–12 hours and 80–100 mg/kg/day of aspirin in four divided doses. The duration of high-dose aspirin is institution-dependent: many centers reduce the dose once the patient is afebrile for 48–72 hours; others continue through 5 afebrile days or day 14 of the illness. Once high-dose aspirin is institution-dependent: many centers reduce the dose once the patient is afebrile for 48–72 hours; others continue through 5 afebrile days or day 14 of the illness. Once high-dose aspirin is discontinued, low-dose aspirin (3–5 mg/kg/day) is given through the subacute phase of the illness (6–8 weeks) or until coronary artery abnormalities resolve. If fever recurs within 48–72 hours of the initial treatment course and no other source of the fever is detected, a second dose of IVIG is often recommended; however, the effectiveness of this approach has not been clearly demonstrated. Corticosteroids or other anti-inflammatory therapy (eg, infliximab) should be considered for patients with persistent fever despite one or two infusions of IVIG. Follow up of patients with treated Kawasaki disease depends on the degree of coronary involvement (Table 20–15).

**INFECTIVE ENDOCARDITIS**

### ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Positive blood culture.
- Intracardiac oscillating mass, abscess, or new valve regurgitation on echocardiogram.
- Fever.
- Elevated erythrocyte sedimentation rate or C-reactive protein.

### General Considerations

Bacterial or fungal infection of the endocardium of the heart is rare and usually occurs in the setting of a preexisting abnormality of the heart or great arteries. It may occur in a normal heart during septicemia or as a consequence of infected indwelling central catheters.
The frequency of infective endocarditis (IE) appears to be increasing for several reasons: (1) increased survival in children with congenital heart disease, (2) greater use of central venous catheters, and (3) increased use of prosthetic material and valves. Pediatric patients without preexisting heart disease are also at increased risk for IE because of (1) increased survival rates for children with immune deficiencies, (2) long-term use of indwelling lines in ill newborns and patients with chronic diseases, and (3) increased intravenous drug abuse.

Patients at greatest risk are children with unrepaired or palliated cyanotic heart disease (especially in the presence of an aorta to pulmonary shunt), those with implanted prosthetic material, and patients who have had a prior episode of IE. Common organisms causing IE are viridans streptococci (30%–40% of cases), Staphylococcus aureus (25%–30%), and fungal agents (about 5%).

**Clinical Findings**

**A. History**

The majority of patients with IE have a history of heart disease. There may or may not be an antecedent infection or surgical procedure (cardiac surgery, tooth extraction, tonsillectomy). Transient bacteremia occurs frequently during normal daily activities such as flossing or brushing teeth, using a toothpick and even when chewing food. Although dental and nonsterile surgical procedures also can result in transient bacteremias, these episodes are much less frequent for a given individual. This may be why a clear inciting event is often not identified in association with IE and also underlies the recent changes in guidelines for antibiotic prophylaxis to prevent IE (for details, see Wilson et al reference).

**B. Symptoms, Signs, and Laboratory Findings**

Although IE can present in a fulminant fashion with cardiovascular collapse, often it presents in an indolent manner with fever, malaise, and weight loss. Joint pain and vomiting are less common. On physical examination, there may be a new or changing murmur, splenomegaly, and hepatomegaly. Classic findings of Osler nodes (tender nodules, usually on the pulp of the fingers), Janeway lesions (nonfuscular hemorrhagic macules on palms and soles), splinter hemorrhages, and Roth spots (retinal hemorrhage) are uncommonly noted in children. Laboratory findings include multiple positive blood cultures, elevated erythrocyte sedimentation rate or C-reactive protein, and hematuria. Transthoracic echocardiography can identify large vegetations in some patients, but transesophageal imaging has better sensitivity and may be necessary if the diagnosis remains in question.

</tr>
</tbody>
</table>

**Prevention**

In 2007, the AHA revised criteria for patients requiring prophylaxis for IE (Table 20–16). Only the high-risk patients listed require antibiotics before dental work (tooth extraction or cleaning) and procedures involving the respiratory tract or infected skin or musculoskeletal structures. IE prophylaxis is not recommended for gastrointestinal or genitourinary procedures, body piercing, or tattooing.

Recommended prophylaxis is 50 mg/kg of oral amoxicillin for patients < 40 kg and 2000 mg for those > 40 kg. This dose is to be given 1 hour prior to procedure. If the patient is allergic to amoxicillin, alternative prophylactic antibiotics are recommended in the AHA guidelines.

**Treatment**

In general, appropriate antibiotic therapy should be initiated as soon as IE is suspected and several large volume blood cultures have been obtained via separate venipunctures. Therapy can be tailored once the pathogen and sensitivities are defined. Vancomycin or a β-lactam antibiotic, with or without gentamicin, for a 6-week course is the most common regimen. If HF occurs and progresses in the face of adequate antibiotic therapy, surgical excision of the infected area and prosthetic valve replacement must be considered.

**Course & Prognosis**

Factors associated with a poor outcome are delayed diagnosis, presence of prosthetic material, perioperative associated IE, and S aureus infection. Mortality for bacterial endocarditis in children ranges from 10% to 25%, with fungal infections having a much greater mortality (50% or more).

PERICARDITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

» Chest pain made worse by deep inspiration and decreased by leaning forward.
» Fever and tachycardia.
» Shortness of breath.
» Pericardial friction rub.
» ECG with elevated ST segments.

General Considerations
Pericarditis is an inflammation of the pericardium and is commonly related to an infectious process. The most common cause of pericarditis in children is viral infection (eg, coxsackievirus, mumps, Epstein-Barr, adenovirus, influenza, and human immunodeficiency virus [HIV]). Purulent pericarditis results from bacterial infection (eg, pneumococci, streptococci, staphylococci, and Hemophilus influenzae) and is less common but potentially life-threatening.

In some cases, pericardial disease occurs in association with a generalized process. Associations include rheumatic fever, rheumatoid arthritis, uremia, systemic lupus erythematosus, malignancy, and tuberculosis. Pericarditis after cardiac surgery (postpericardiotomy syndrome) is most commonly seen after surgical closure of an ASD. Postpericardiotomy syndrome appears to be autoimmune in nature with high titers of antiheart antibody and evidence of acute or reactivated viral illness. The syndrome is often self-limited and responds well to short courses of aspirin or corticosteroids.

Clinical Findings
A. Symptoms and Signs
Childhood pericarditis usually presents with sharp stabbing mid chest, shoulder, and neck pain made worse by deep inspiration or coughing, and decreased by sitting up and leaning forward. Shortness of breath and grunting respirations are common. Physical findings depend on the presence of fluid accumulation in the pericardial space (effusion). In the absence of significant accumulation, a characteristic scratchy, high-pitched friction rub may be heard. If the effusion is large, heart sounds are distant and muffled and a friction rub may not be present. In the absence of cardiac tamponade, the peripheral, venous, and arterial pulses are normal.

Cardiac tamponade occurs in association with a large effusion, or one that has rapidly accumulated. Tamponade is characterized by jugular venous distention, tachycardia, hepatomegaly, peripheral edema, and pulsus paradoxus, in which systolic blood pressure drops more than 10 mm Hg during inspiration. Decreased cardiac filling and subsequent decrease in cardiac output result in signs of right heart failure and the potential for cardiovascular collapse.

B. Imaging
In pericarditis with a significant pericardial effusion, the cardiac silhouette is enlarged. The cardiac silhouette can appear normal if the effusion has developed over an extremely short period of time.

C. Electrocardiography
The ST segments are commonly elevated in acute pericarditis and PR segment depression may be present. Low voltages or electrical alternans (alteration in QRS amplitude between beats) can be seen with large pericardial effusions.

D. Echocardiography
Serial echocardiography allows a direct, noninvasive estimate of the volume of pericardial fluid and its change over time. Cardiac tamponade is associated with compression of the atria or respiratory alteration of ventricular inflow demonstrated by Doppler imaging.

Treatment
Treatment depends on the cause of pericarditis and the size of the associated effusion. Viral pericarditis is usually self-limited and symptoms can be improved with nonsteroidal anti-inflammatory therapy. Purulent pericarditis requires immediate evacuation of the fluid and appropriate antibiotic therapy. Cardiac tamponade from any cause must be treated by immediate removal of the fluid, usually via pericardiocentesis. Pericardiocentesis should also be considered if the underlying cause is unclear or identification of the pathogen is necessary for targeted therapy. In the setting of recurrent or persistent effusions, a surgical pericardiectomy or pericardial window may be necessary. Diuretics should be avoided in the patient with cardiac tamponade because they reduce ventricular preload and can exacerbate the degree of cardiac decompensation.

Prognosis
Prognosis depends to a great extent on the cause of pericardial disease. Constrictive pericarditis can develop following infectious pericarditis (especially if bacterial or tuberculous) and can be a difficult problem to manage. Cardiac tamponade will result in death unless the fluid is evacuated.

CARDIOMYOPATHY

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► Failure to thrive
► Poor appetite, abdominal pain and/or vomiting
► Exercise Intolerance
► Tachypnea, cough, orthopnea and/or shortness of breath
► Diaphoresis
► Edema
► Tachycardia
► Fainting or aborted sudden death event
► Diagnosis based on echocardiographic findings

There are five classified forms of cardiomyopathy in children: (1) dilated, (2) hypertrophic, (3) restrictive, (4) arrhythmogenic right ventricular dysplasia (ARVD), and (5) left ventricular noncompaction. Discussion will be limited to the first three forms, which are the most common.

1. Dilated Cardiomyopathy

This most frequent of the childhood cardiomyopathies occurs with an annual incidence of 4–8 cases per 100,000 population in the United States and Europe. Although usually idiopathic, identifiable causes of dilated cardiomyopathy (DCM) include viral myocarditis, untreated tachyarrhythmias, left heart obstructive lesions, congenital abnormalities of the coronary arteries, medication toxicity (eg, anthracycline), and genetic (eg, dystrophin gene defects, sarcomeric mutations) and metabolic diseases (inborn errors of fatty acid oxidation and mitochondrial oxidative phosphorylation defects). Genetic causes are being discovered at an increasing rate with commercial testing now available for some of the more common genes.

Clinical Findings

A. Signs and Symptoms

As myocardial function fails and the heart dilates, cardiac output falls, and affected children develop decreased exercise tolerance, failure to thrive, diaphoresis, and tachypnea. As the heart continues to deteriorate, congestive signs such as hepatomegaly and rales develop, and a prominent gallop can be appreciated on examination. The initial diagnosis in a previously healthy child can be difficult, as presenting symptoms can resemble a viral respiratory infection, pneumonia, or asthma.

B. Imaging

Chest radiograph shows generalized cardiomegaly with or without pulmonary venous congestion.

C. Electrocardiography

Sinus tachycardia with ST-T segment changes is commonly seen on ECG. The criteria for right and left ventricular hypertrophy may also be met and the QT interval may be prolonged. Evaluation for the presence of supraventricular arrhythmias on ECG is critical, as this is one of the few treatable and reversible causes of DCM in children.

D. Echocardiography

The echocardiogram shows LV and left atrial enlargement with decreased LV-shortening fraction and ejection fraction. The calculated end-diastolic and end-systolic dimensions are increased and mitral insufficiency is commonly seen. A careful evaluation for evidence of structural abnormalities (especially coronary artery anomalies or left heart obstructive lesions) must be performed, especially in infant patients.

E. Other Testing

Cardiac catheterization is useful to evaluate hemodynamic status and coronary artery anatomy. Endomyocardial biopsies can aid in diagnosis. Biopsy specimens may show inflammation consistent with acute myocarditis, abnormal myocyte architecture, and myocardial fibrosis. Electron micrographs may reveal evidence of mitochondrial or other metabolic disorders. Polymerase chain reaction (PCR) testing may be performed on biopsied specimens to detect viral genome products in infectious myocarditis. Cardiopulmonary stress testing is useful for measuring response to medical therapy and as an objective assessment of the cardiac limitations on exercise.

Treatment & Prognosis

Outpatient management of pediatric DCM usually entails combinations of afterload-reducing agents and diuretics.
(see section on Heart Failure, earlier). In 2007, Shaddy et al published the results of a multicenter, placebo-controlled, double-blind trial of carvedilol in children with HF. Children did not receive the same beneficial effects of β-blocker therapy as adults with HF, possibly due to the heterogeneous nature of HF in children and increasing evidence that there are inherent differences in pediatric and adult HF. Aspirin or warfarin may be used to prevent thrombus formation in the dilated and poorly contractile cardiac chambers. Arrhythmias are more common in dilated hearts and antiarrhythmic therapy is sometimes necessary. Despite widespread use of internal defibrillators in the adult population, the technical difficulty of implanting internal defibrillators, the risk of adverse events (e.g., high frequency of inappropriate discharge, vascular obstruction), and the low incidence of sudden cardiac death in children limit their use.

Therapy of the underlying cause of cardiomyopathy is always indicated if possible. Unfortunately despite complete evaluation, a diagnosis is discovered in less than 30% of patients with DCM. If medical management is unsuccessful, cardiac transplantation is considered.

2. Hypertrophic Cardiomyopathy

The most common cause of hypertrophic cardiomyopathy (HCM) is familial hypertrophic cardiomyopathy, which is found in 1 in 500 individuals. HCM is the leading cause of sudden cardiac death in young persons. The most common presentation is in an older child, adolescent, or adult, although it may occur in neonates. Causes of nonfamilial HCM in neonates and young children include glycogen storage disease, Noonan syndrome (including related syndromes such as LEOPARD and Costello syndrome), Friedreich ataxia, maternal gestational diabetes, mitochondrial disorders, and other metabolic disorders.

A. Familial Hypertrophic Cardiomyopathy

In the familial form, HCM is most commonly caused by a mutation in one of the several genes that encode proteins of the cardiac sarcomere (β-myosin heavy chain, cardiac troponin T or I, α-tropomyosin, and myosin-binding protein C).

1. Clinical Findings—Patients may be asymptomatic despite having significant hypertrophy, or may present with symptoms of inadequate coronary perfusion or HF such as angina, syncope, palpitations, or exercise intolerance. Patients may experience sudden cardiac death as their initial presentation, often precipitated by sporting activities. Although the cardiac examination may be normal on presentation, some patients develop a left precordial bulge with a diffuse point of maximal impulse. An LV heave or an S4 gallop may be present. If outflow tract obstruction exists, a systolic ejection murmur will be audible. A murmur may not be audible at rest but may be provoked with exercise or positional maneuvers that decrease left ventricular volume (standing), thereby increasing the outflow tract obstruction.

A. Echocardiography—The diagnosis of HCM is usually made by echocardiography and in most familial cases demonstrates asymmetrical septal hypertrophy. Young patients with metabolic or other nonfamilial causes are more likely to have concentric hypertrophy. Systolic anterior motion of the mitral valve leaflet may occur and contribute to LV outflow tract obstruction. The mitral valve leaflet may become distorted and result in mitral insufficiency. LV outflow tract obstruction may be present at rest or provoked with monitored exercise. Systolic function is most often hypercontractile in young children but may deteriorate over time, resulting in poor contractility and LV dilation. Diastolic function is almost always abnormal.

B. Electrocardiography—The ECG may be normal, but more typically demonstrates deep Q waves in the inferolateral leads (II, III, aVF, V5, and V6) secondary to the increased mass of the hypertrophied septum. ST-segment abnormalities may be seen in the same leads. Age-dependent criteria for LVH are often present as are criteria for left atrial enlargement.

C. Other Testing—Cardiopulmonary stress testing is valuable to evaluate for provokable LV outflow tract obstruction, ischemia, and arrhythmias, and to determine prognosis. Extreme LVH and a blunted blood pressure response to exercise have both been associated with increased mortality in children. Cardiac MRI is useful for defining areas of myocardial fibrosis or scarring. Patients are at risk for myocardial ischemia, possibly as a result of systolic compression of the intramyocardial septal perforators, myocardial bridging of epicardial coronary arteries, or an imbalance of coronary artery supply and demand due to the presence of massive myocardial hypertrophy.

D. Cardiac Catheterization—Cardiac catheterization may be performed in patients with HCM who have angina, syncope, resuscitated sudden death, or a worrisome stress test. Hemodynamic findings include elevated left atrial pressure secondary to impaired diastolic filling. If midcavitary LV outflow tract obstruction is present, an associated pressure gradient will be evident. Provocation of LV outflow tract obstruction with either rapid atrial pacing or isoproterenol may be sought, but this is not commonly done in children. Angiography demonstrates a “ballerina slipper” configuration of the LV secondary to the midcavitary LV obliteration during systole. Although uncommonly done in the current era, myocardial biopsy demonstrates myofiber disarray.
2. Treatment and prognosis—Treatment varies depending on symptoms and phenotype. Affected patients are restricted from competitive athletics and isometric exercise due to associated risk of sudden cardiac death. Patients with resting or latent LV outflow tract obstruction may be treated with β-blockers, verapamil, or disopyramide with variable success in alleviating obstruction. Patients with severe symptoms despite medical therapy and an LV outflow tract gradient may require additional intervention. Surgical myectomy with resection of part of the hypertrophied septum has been used in symptomatic patients with good results. At the time of myectomy, the mitral valve may require repair or replacement in patients with a long history of systolic anterior motion of the mitral valve. Ethanol ablation is used in adults with HCM and LV outflow tract obstruction. This procedure involves selective infiltration of ethanol in a coronary septal artery branch to induce a small targeted myocardial infarction. This leads to a reduction in septal size and improvement of obstruction. The long-term effects of this procedure are unknown and it is not commonly employed in children. Dual-chamber pacing to relieve obstruction has been used in children, but data to support its use is lacking. Risk stratification with respect to sudden death is important in HCM. Consideration for placement of internal defibrillators in adult patients are based on the known risk factors for sudden cardiac death: severe hypertrophy (> 3 cm septal thickness in adults), documented ventricular arrhythmias, syncope, abnormal blood pressure response to exercise, resuscitated sudden death, or a strong family history of HCM with associated sudden death. The criteria for defibrillator placement in children are not as well defined.

B. Glycogen Storage Disease of the Heart

There are at least 10 types of glycogen storage disease. The type that primarily involves the heart is Pompe disease (GSD IIa) in which acid maltase, necessary for hydrolysis of the outer branches of glycogen, is absent. There is marked deposition of glycogen within the myocardium. Affected infants are well at birth, but symptoms of growth and developmental delay, feeding problems, and cardiac failure occur by the sixth month of life. Physical examination reveals generalized muscular weakness, a large tongue, and cardiomegaly without significant heart murmurs. Chest radiographs reveal cardiomegaly with or without pulmonary venous congestion. The ECG shows a short PR interval and LVH with ST depression and T-wave inversion over the left precordial leads. Echocardiography shows severe concentric LVH. Although historically children with Pompe disease usually died before age 1 year, recent enzyme replacement clinical trials have shown some promise in reversing hypertrophy and preserving cardiac function. Death may be sudden or result from progressive HF.

3. Restrictive Cardiomyopathy

Restrictive cardiomyopathy is a rare entity in the pediatric population, accounting for less than 5% of all cases of cardiomyopathy. The cause is usually idiopathic but can be familial or secondary to an infiltrative process (eg, amyloidosis).

Clinical Findings

Patients present with signs of congestive HF as a consequence of diastolic dysfunction in the setting of preserved systolic function. The left ventricle is more severely affected than the right ventricle in restrictive cardiomyopathy, but the right ventricle is also affected in most cases resulting in signs and symptoms consistent with biventricular congestion. Patients often present with exercise intolerance, fatigue, chest pain and orthopnea. Physical examination is remarkable for a prominent S4 and jugular venous distention.

A. Electrocardiography

ECG demonstrates marked right and left atrial enlargement with normal ventricular voltages. ST-T-wave abnormalities including a prolonged QTc interval may be present.

B. Echocardiography

The diagnosis is confirmed echocardiographically by the presence of normal-sized ventricles with normal systolic function and massively dilated atria. Cardiac MRI is useful in ruling out pericardial abnormalities (restrictive or constrictive pericarditis) and infiltrative disorders.

Treatment & Prognosis

Anticongestive therapy is used for symptomatic relief. The risk of sudden death in restrictive cardiomyopathy and the propensity for rapid progression of irreversible pulmonary hypertension warrant close follow-up with early consideration of cardiac transplantation.

CHAPTER 20

MYOCARDITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Often occurs in association with a viral infection.
- Signs and symptoms of cardiomyopathy as outlined earlier.
- Echocardiogram will demonstrate a poorly functioning ventricle with varying degrees of ventricular dilation.
- May see diffusely low voltages on ECG.
- Elevated inflammatory markers may be present (eg ESR, CRP).
- Cardiac MRI is an evolving diagnostic tool.
- Endomyocardial biopsy will demonstrate lymphocytic infiltrate and viral PCR positivity.

The most common causes of viral myocarditis are adenoviruses, coxsackie A and B viruses, echoviruses, parvovirus, cytomegalovirus, and influenza A virus. HIV can also cause myocarditis. The ability to identify the pathogen has been enhanced by PCR technology, which replicates identifiable segments of the viral genome from the myocardium of affected children.

» Clinical Findings

A. Symptoms and Signs

There are two major clinical patterns. In the first, sudden-onset HF occurs in an infant or child who was relatively healthy in the hours to days previously. This malignant form of the disease is usually secondary to overwhelming viremia with tissue invasion in multiple organ systems including the heart. In the second pattern, the onset of cardiac symptoms is gradual and there may be a history of upper respiratory tract infection or gastroenteritis in the previous month. This more insidious form may have a late postinfectious or autoimmune component. Acute and chronic presentations occur at any age and with all types of myocarditis.

The signs of HF are variable, but in a decompensated patient with fulminating myocarditis include pale gray skin; rapid, weak, and thready pulses; and breathlessness. In those with a more subacute presentation signs include increased work of breathing such as orthopnea, difficulty with feeding in infants, exercise intolerance and edema of the face and extremities. The patient is usually tachycardic and heart sounds may be muffled and distant; an S3 or S4 gallop (or both) are common. Murmurs are usually absent, although a murmur of tricuspid or mitral insufficiency may be heard. Moist rales are usually present at both lung bases. The liver is enlarged and frequently tender.

B. Imaging

Generalized cardiomegaly is seen on radiographs along with moderate to marked pulmonary venous congestion.

C. Electrocardiography

The ECG is variable. Classically, there is low-voltage QRS in all frontal and precordial leads with ST-segment depression and inversion of T waves in leads I, III, and aVF (and in the left precordial leads during the acute stage). Dysrhythmias are common, and AV and intraventricular conduction disturbances may be present.

D. Echocardiography

Echocardiography demonstrates four-chamber dilation with poor ventricular function and AV valve regurgitation. A pericardial effusion may be present. Patients with a more acute presentation may have less ventricular dilation than those with a longer history of HF-related symptoms.

E. Myocardial Biopsy

An endomyocardial biopsy may be helpful in the diagnosis of viral myocarditis. An inflammatory infiltrate with myocyte damage can be seen by hematoxylin and eosin staining. Viral PCR testing of the biopsy specimen may yield a positive result in 30%–40% of patients suspected to have myocarditis. However, myocarditis is thought to be a “patchy” process, so it is possible that biopsy results are falsely negative if the area of active myocarditis was missed.

F. Cardiac MRI

Cardiac MRI is increasing in use as a potential diagnostic modality for myocarditis. Abnormalities in T2-weighted imaging (consistent with myocardial edema, inflammation) and global relative enhancement (evidence of capillary leak) are evident in patients with acute myocarditis. This imaging method requires general anesthesia in infants and young children, which is associated with significant risk in those with HF and must be a consideration when ordering this test.

» Treatment

The inpatient cardiac support measures outlined previously in the section on heart failure are used in the treatment of these patients. The use of digitalis in a rapidly deteriorating child with myocarditis is dangerous and should be undertaken with great caution, as it may cause ventricular dysrythmias.
Administration of immunomodulating medications such as corticosteroids for myocarditis is controversial. Subsequent to the successful use of IVIG in children with Kawasaki disease, there have been several trials of IVIG in presumed viral myocarditis. The therapeutic value of IVIG remains unconfirmed. Initiation of mechanical circulatory support in those with fulminant or severe myocarditis is another therapeutic option as a bridge to transplantation or recovery.

**Prognosis**

The prognosis of myocarditis is determined by the age at onset and the response to therapy. Children presenting with fulminant myocarditis and severe hemodynamic compromise have a 75% early mortality. Those at highest risk for a poor outcome are those presenting in the first year of life. Complete recovery is possible, although some patients recover clinically but have persistent LV dysfunction and require ongoing medical therapy for HF. It is possible that subclinical myocarditis in childhood is the pathophysiologic basis for some of the "idiopathic" DCMs later in life. Children with myocarditis whose ventricular function fails to return to normal may be candidates for cardiac transplantation if they remain symptomatic or suffer growth failure despite maximal medical management.

**PREVENTIVE CARDIOLOGY**

**HYPERTENSION**

Blood pressure should be determined at every pediatric visit beginning at 3 years. Because blood pressure is being more carefully monitored, systemic hypertension has become more widely recognized as a pediatric problem. Pediatric standards for blood pressure have been published. Blood pressures in children must be obtained when the child is relaxed and an appropriate-size cuff must always be used. The widest cuff that fits between the axilla and the antecubital fossa should be used (covers 60%–75% of the upper arm). Most children aged 10–11 years need a standard adult cuff (bladder width of 12 cm), and many high school students need a large adult cuff (width of 16 cm) or leg cuff (width of 18 cm). The pressure coinciding with the onset (K₁) and the loss (K₅) of the Korotkoff sounds determines the systolic and diastolic blood pressure, respectively. If a properly measured blood pressure exceeds the 95th percentile, the measurement should be repeated several times over a 2- to 4-week interval. If it is elevated persistently, a search for the cause should be undertaken. Although most hypertension in children is essential, the incidence of treatable causes is higher in children than in adults; these include conditions such as coarctation of the aorta, renal artery stenosis, chronic renal disease, and pheochromocytoma, as well as medication side effects (eg, steroids). If no cause is identified, and hypertension is deemed essential, antihypertensive therapy should be initiated and nutritional and exercise counseling given. β-Blockers or ACE inhibitors are the usual first-line medical therapies for essential hypertension in children.

**ATHEROSCLEROSIS & DYSLIPIDEMIAS**

Awareness of coronary artery risk factors in general, and atherosclerosis in particular, has risen dramatically in the general population since the mid-1970s. Although coronary artery disease is still the leading cause of death in the United States, the age-adjusted incidence of death from ischemic heart disease has been decreasing as a result of improved diet, decreased smoking, awareness and treatment of hypertension, and an increase in physical activity. The level of serum lipids in childhood usually remains constant through adolescence. Biochemical abnormalities in the lipid profile appearing early in childhood correlate with higher risk for coronary artery disease in adulthood. Low-density lipoprotein (LDL) is atherogenic, while its counterpart, high-density lipoprotein (HDL) has been identified as an anti-atherogenic factor.

Routine lipid screening of children at age 3 years remains controversial. The National Cholesterol Education Program recommends selective screening in children with high-risk family members, defined as a parent with total cholesterol greater than 240 mg/dL or a parent or grandparent with early-onset cardiovascular disease. When children have LDL levels greater than 130 mg/dL on two successive tests, dietary lifestyle counseling is appropriate. Dietary modification may decrease cholesterol levels by 5%–20%. If the patient is unresponsive to diet change and at extreme risk (eg, LDL > 160 mg/dL, HDL < 35 mg/dL, and a history of cardiovascular disease in a first-degree relative at an age < 40 years), drug therapy may be indicated. Cholestyramine, a bile acid-binding resin, is rarely used today due to poor adherence. The 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (statins) are more commonly used in the pediatric population. Niacin is useful for treatment of hypertriglyceridemia.

by inflammation of the costochondral joints, and is reproducible on examination. Respiratory causes include reactive airway disease, pneumonia, pleuritis, and pneumothorax. Gastrointestinal causes of chest pain include reflux, esophagitis, gastritis, foreign body ingestion, hiatal hernia, cholecystitis, and referred abdominal pain. Hematology-oncology conditions include pulmonary embolism, sickle cell anemia and tumors. Psychological conditions are more common in adolescents than younger children and include stress, anxiety, panic attacks, somatoform disorder, and depression.

Cardiac disease is itself an infrequent cause of chest pain; however, if misdiagnosed, it may be life-threatening. Although myocardial infarction very rarely occurs in children, it is possible. Often, it is related to substance abuse and/or coronary vasospasm. Abnormal origins of the coronary arteries can be associated with chest pain and sudden cardiac death. Coronary arteries may arise from the wrong sinus of Valsalva in the aortic root, with a slit-like orifice and narrowed, intramural course within the wall of the aorta. They may also arise from another coronary artery with a course that traverses between the aorta and pulmonary artery, which can limit flow during exercise. Even in the setting of normal coronary artery origins, particular medical conditions can put one at increased risk for myocardial infarction. A history of Kawasaki disease with coronary artery involvement puts one at risk for future myocardial infarction secondary to thrombosis of coronary aneurysms. Arrhythmias can also elicit chest pain, and young children may simply describe the palpitations associated with an arrhythmia as chest pain. Arrhythmias that can be associated with chest pain include the following: supraventricular tachycardia (SVT), including atrioventricular reentrant tachycardia (AVRT), atrioventricular nodal reentrant tachycardia (AVNRT), atrial flutter, and ectopic atrial tachycardia; ventricular tachycardia; complete heart block; or simple ectopy, including premature atrial or ventricular contractions (PACs, PVCs). Structural lesions that can cause chest pain include left ventricular outflow tract obstruction, including aortic stenosis, and pulmonary stenosis. Other cardiac conditions that can cause chest pain include dilated cardiomyopathy, myocarditis, pericarditis, rheumatic carditis, and aortic dissection.

Evaluation

In most cases, sophisticated testing is not required. However, if a cardiac origin is suspected, a pediatric cardiologist should be consulted. Evaluation in these instances may include an ECG, chest radiograph, echocardiogram, Holter or transient arrhythmia monitor, or serum troponin levels if there are known risk factors for ischemia. In a 10 year study of 3,700 patients evaluated in a pediatric cardiology clinic, only 1% of patients were found to have a cardiac etiology to their chest pain; the vast majority of these patients

Overview

Chest pain is a common pediatric complaint, accounting for 3–6 in 1000 visits to urban emergency departments and urgent care clinics, with median age of 12–13 years and a male predominance (1-1.6:1). Although children with chest pain are commonly referred for cardiac evaluation, chest pain in children is uncommonly cardiac in origin, with a cardiac etiology found in only 2–5% of emergency department visits and 3–7% of cardiology clinic visits. Detailed history and physical examination should guide the pediatrician to the appropriate workup of chest pain. The location, duration, intensity, frequency, and radiation of the pain should be documented, as well as associated symptoms and any possible worsening or alleviating factors. The presence of triggering events preceding the pain should be explored. Chest pain during or immediately following exertion should lead to a more elaborate evaluation for a cardiac disorder. Associated symptoms should be evaluated, including syncope, palpitations, nausea/vomiting, shortness of breath, cough, or wheezing. Relation of pain to meals should be investigated. Detailed social history may reveal psychosocial stressors or exposures such as smoking or drug abuse. On physical examination, attention must be placed on the following: vital signs; general appearance of the child; the chest wall morphology & musculature; cardiac, pulmonary, and abdominal examination findings; and quality of peripheral pulses. If the pain can be reproduced through direct palpation of the chest wall, it is almost always musculoskeletal in origin.

Etiology

Chest pain is typically non-cardiac and may be due to a multitude of conditions. Most commonly, no identifiable cause is found (idiopathic chest pain), despite sometimes extensive evaluations. Musculoskeletal etiologies are the most common identifiable cause of chest pain and include costochondritis, muscular strain, skeletal abnormality, and trauma, among others. Costochondritis (or Tietze syndrome) accounts for 26–41% of chest pain cases, is caused
had suggestive symptoms (eg, exertional chest pain), concerning family/medical history, abnormal examination, or abnormal electrocardiogram. Forty percent of patients underwent echocardiography; incidental cardiac findings (unrelated to chest pain) were found in 4% of all patients and a positive finding potentially related to the complaint of chest pain was found in only 0.3% of patients. Rhythm monitors were positive in only 0.4% of patients, most of whom had complaints of palpitations. Exercise stress test was not additive to making a diagnosis. There were no sudden cardiac deaths in any of the 3,700 patients who presented with chest pain; children were more likely to die from suicide, confirming that depression and anxiety are potential serious causes of chest pain.

CARDIOVASCULAR DISEASES

Cardiac transplantation is an effective therapeutic modality for infants and children with end-stage cardiac disease. Indications for transplantation include (1) progressive HF despite maximal medical therapy, (2) complex congenital heart diseases that are not amenable to surgical repair or palliation, or in instances in which the surgical palliative approach has an equal or higher risk of mortality compared with transplantation, and (3) malignant arrhythmias unresponsive to medical therapy, catheter ablation, or automatic implantable cardioverter-defibrillator. Approximately 300–400 pediatric cardiac transplant procedures are performed annually in the United States. Infant (< 1 year of age) transplants account for 30% of pediatric cardiac transplants. The current estimated graft half-life for children undergoing cardiac transplantation in infancy is over 19 years, while overall pediatric heart transplant graft half-life is approximately 14 years.

Careful evaluation of the recipient and the donor is performed prior to cardiac transplantation. Assessment of the recipient’s pulmonary vascular resistance is critical, as irreversible and severe pulmonary hypertension is a risk factor for post-transplant right heart failure and early death. End-organ function of the recipient may also influence post-transplant outcome and should be evaluated. Donor-related factors that can have an impact on outcome include cardiac function, amount of inotropic support needed, active infection (HIV and hepatitis B and C are contraindications to organ donation), donor size, and ischemic time to transplantation.

Immunosuppression

The ideal post-transplant immunosuppressive regimen allows the immune system to continue to recognize and respond to foreign antigens in a productive manner while avoiding graft rejection. Although there are many different regimens, calcineurin inhibitors (eg, cyclosporine and tacrolimus) remain the mainstay of maintenance immunosuppression in pediatric heart transplantation. Calcineurin inhibitors may be used in isolation in children considered to be at low risk for graft rejection. Double-drug therapy includes the addition of antimitabolite or antiproliferative medications such as azathioprine, mycophenolate mofetil, or sirolimus. Because of the significant adverse side effects of corticosteroids in children, chronic steroid use is avoided if possible. Growth retardation, susceptibility to infection, impaired wound healing, hypertension, diabetes, osteoporosis, and a cushingoid appearance are some of the consequences of long-term steroid use.

Graft Rejection

Despite advances in immunosuppression, graft rejection remains the leading cause of death in the first 3 years after transplantation. Because graft rejection can present in the absence of clinical symptomatology, monitoring for and diagnosing rejection in a timely fashion can be difficult. Screening regimens include serial physical examinations, electrocardiography, echocardiography, and cardiac catheterization with endomyocardial biopsy.

Rejection Surveillance

A. Symptoms and Signs

Acute graft rejection may not cause symptoms in the early stages. With progression, patients may develop tachycardia, tachypnea, rales, a gallop rhythm, or hepatosplenomegaly. Infants and young children may present with irritability, poor feeding, vomiting, or lethargy. There is 50% mortality within 1 year for those suffering an episode of rejection associated with hemodynamic compromise, so early detection is critical.

B. Imaging

In an actively rejecting patient, chest radiographs may show cardiomegaly, pulmonary edema, or pleural effusions.
C. Electrocardiography

Abnormalities in conduction, reduced QRS voltages, and atrial and ventricular arrhythmias can occur in rejection.

D. Echocardiography

Echocardiography is a useful noninvasive rejection surveillance tool. Changes in ventricular compliance and function may initially be subtle, but are progressive with increasing duration of the rejection episode. A new pericardial effusion or worsening valvular insufficiency may also indicate rejection.

E. Cardiac Catheterization and Endomyocardial Biopsy

Hemodynamic assessment including ventricular filling pressures, cardiac output, and oxygen consumption can be obtained via cardiac catheterization. The endomyocardial biopsy is useful in diagnosing acute graft rejection but not all episodes of symptomatic rejection result in a positive biopsy result. The appearance of infiltrating lymphocytes with myocardial damage on the biopsy is the hallmark of cell-mediated graft rejection and is helpful if present.

Treatment of Graft Rejection

The goal of graft rejection treatment is to reverse the immunologic inflammatory cascade. High-dose corticosteroids are the first line of treatment. Frequently additional therapy with antithymocyte biologic preparations such as antithymocyte globulin (a rabbit-based polyclonal antibody) is needed to reverse rejection. Most rejection episodes can be treated effectively if diagnosed promptly. Usually graft function returns to its baseline state, although severe rejection episodes can result in chronic graft failure, graft loss, and patient death even with optimal therapy. Antibody mediated rejection is another form of acute rejection that is treated in a similar fashion as T-cell mediated rejection, but the addition of plasmapheresis and IVIG to the treatment regimen may improve outcomes. The diagnosis of antibody mediated rejection is complicated, but is based on a combination of clinical symptoms, evidence of complement deposition on endomyocardial biopsy, and new or increasing antibody production (typically anti-human lymphocyte antigen [HLA] antibodies) in the circulation.

Course & Prognosis

The quality of life of pediatric heart transplant recipients is usually quite good. The risk of infection is low after the immediate post-transplant period in spite of chronic immunosuppression. Cytomegalovirus is the most common pathogen responsible for infection-related morbidity and mortality in heart transplant recipients. Most children tolerate environmental pathogens well. Nonadherence with lifetime immunosuppression is of great concern especially in adolescent patients. Several recent studies have identified nonadherence as the leading cause of late death. Post-transplant lymphoproliferative disorder, a syndrome related to Epstein-Barr virus infection, can result in a Burkitt-like lymphoma that usually responds to a reduction in immunosuppression, but occasionally must be treated with chemotherapy and can be fatal. The overwhelming majority of children are not physically limited and do not require restrictions related to the cardiovascular system.

The most common cause of late graft loss is cardiac allograft vasculopathy (transplant coronary artery disease). Cardiac allograft vasculopathy results from intimal proliferation within the lumen of the coronary arteries that can ultimately result in complete luminal occlusion. These lesions are diffuse and often involve distal vessels and thus are usually not amenable to bypass grafting, angioplasty, or stent placement. The etiology of these lesions has an immune basis, but the specifics are not known making targeted therapy challenging. Newer, more specific, and more effective immunosuppressive agents are currently being tried in clinical studies or are being evaluated in preclinical studies, making the future promising for children after cardiac transplantation.

QUALITY IMPROVEMENT FOR PEDIATRIC HEART TRANSPLANTATION

The Pediatric Heart Transplant Study (PHTS) group is a consortium of over 40 pediatric heart transplant centers in North America and Europe that maintains an event-driven database that is used to support research aimed at improving treatment options and outcomes for children in need of a heart transplant or who have had a transplant. Each participating center receives an annual report that details center-specific outcomes compared to the collaborative group as a whole. This report is utilized for internal quality assurance purposes and as a performance benchmark.

Canter CE et al: Indications for heart transplantation in pediatric heart disease: a scientific statement from the American Heart Association Council on Cardiovascular Disease in the Young; the Councils on Clinical Cardiology, Cardiovascular Nursing, and Cardiovascular Surgery and Anesthesia; and the Quality of Care and Outcomes Research Interdisciplinary Working Group. Circulation Feb 6, 2007;115(5):658–676 [PMID: 17261651].

PULMONARY HYPERTENSION

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

» Often subtle with symptoms of dyspnea, fatigue, chest pain, and syncope.
» Loud pulmonary component of S₂; ECG with RVH.
» Rare, progressive, and often fatal disease without treatment.

General Considerations

Pulmonary hypertension (PH) is defined as an increase in mean pulmonary artery pressure (PAP) ≥ 25 mm Hg. The etiology of PH in children is very different from adults, with a predominance of idiopathic pulmonary arterial hypertension (IPAH) and pulmonary arterial hypertension (PAH) associated with congenital heart disease. PAH, a subset of PH, affects the pulmonary arterial tree and is defined as a sustained mean PAP ≥ 25 mm Hg with a mean pulmonary capillary wedge pressure ≤ 15 mm Hg and pulmonary vascular resistance > 3 woods units. A diagnostic classification has been developed and modified at the World Symposium on Pulmonary Hypertension (WSPH). This clinical classification system identifies five categories of disorders that cause PH, with each group sharing similar hemodynamic, pathologic, and management features: Pulmonary arterial hypertension (PAH) (Group 1); PH due to left heart disease (Group 2); PH due to chronic lung disease and/or hypoxia (Group 3); chronic thromboembolic PH (Group 4); and PH due to multifactorial mechanisms (Group 5). The incidence of IPAH and PAH associated with congenital heart disease is 1–2 persons per million. PH is difficult to diagnose in the early stages because of its subtle manifestations. Although the outcome for pediatric PH is improving due to the advent of new therapies, prognosis remains guarded, with only 74% survival at 5 years. Familial PH occurs in 6%–12% of affected individuals. When a clear familial association is known, the disease shows evidence of genetic anticipation, presenting at younger ages in subsequent generations.

Clinical Findings

A. Symptoms and Signs

The clinical picture varies with the severity of pulmonary hypertension, and usually early symptoms are subtle, delaying the diagnosis. Initial symptoms may be dyspnea, palpitations, or chest pain, often brought on by strenuous exercise or competitive sports. Syncope may be the first symptom, which usually implies severe disease. As the disease progresses, patients have signs of low cardiac output and right heart failure. Right heart failure may be manifested by hepatomegaly, peripheral edema, and an S₃ gallop on examination. Murmurs of pulmonary regurgitation and tricuspid regurgitation may be present, and the pulmonary component of S₂ is usually pronounced.

B. Imaging

The chest radiograph most often reveals a prominent main pulmonary artery, and the RV may be enlarged. The peripheral pulmonary vascular markings may be normal or diminished. However, in 6% of patients with confirmed PH, the chest radiograph is normal.

C. Electrocardiography

The ECG usually shows RVH with an upright T wave in V₁ (when it should be negative in young children) or a qR complex in lead V₁ or V₃R. Also present may be evidence of right axis deviation and right atrial enlargement.

D. Echocardiography

The echocardiogram is an essential tool for excluding congenital heart disease as a cause of pulmonary hypertension. It frequently shows RVH and dilation. In the absence of other structural disease, tricuspid and PI velocity can be used to estimate pulmonary artery systolic and diastolic pressures, respectively. Other echocardiographic measures such as Tissue Doppler Imaging, myocardial performance index, systolic to diastolic ratio from tricuspid regurgitation velocity, right ventricular to left ventricular ratio in end-systole, and tricuspid annular plane systolic excursion are used in the evaluation of pulmonary hypertension.

E. Cardiac Catheterization and Angiography

Cardiac catheterization is the best method for determining the severity of disease. The procedure is performed to rule out cardiac (eg, restrictive cardiomyopathy) or vascular (eg, pulmonary vein stenosis) causes of pulmonary hypertension, determine the severity of disease, and define treatment strategies. The reactivity of the pulmonary vascular bed to short-acting vasodilator agents (oxygen, nitric oxide, or prostacyclin) can be assessed and used to determine treatment options. Angiography may show a decrease in the number of small pulmonary arteries with tortuous vessels.

F. Other Evaluation Modalities

Cardiac MRI is used in some patients to evaluate right ventricular function, pulmonary artery anatomy, and hemodynamics, as well as thromboembolic phenomena.
Cardiopulmonary exercise testing using cycle ergometry correlates with disease severity. More simply, a 6-minute walk test, in which distance walked and perceived level of exertion are measured, has a strong independent association with mortality in late disease.

**Treatment**

The goal of therapy is to reduce pulmonary artery pressure, increase cardiac output, and improve quality of life. Cardiac catheterization data are used to determine the proper treatment. Patients responsive to pulmonary vasodilators are given calcium channel blockers such as nifedipine or diltiazem. Patients unresponsive to vasodilators initially receive one of three classes of drugs: prostanoids (such as epoprostenol), endothelin receptor antagonists (such as bosentan), or phosphodiesterase-5 inhibitors (such as tadalafil). All of these agents have distinct mechanisms of action that can reduce pulmonary vascular resistance. Warfarin is commonly used for anticoagulation to prevent thromboembolic events, usually with a goal to maintain the INR between 1.5 and 2.0.

Atrial septostomy is indicated in some patients with refractory pulmonary hypertension and symptoms. Cardiac output falls as pulmonary vascular resistance rises, so an interatrial shunt can preserve left heart output, albeit with deoxygenated blood. Lung transplantation should be considered in patients with intractable pulmonary hypertension and in those with associated anatomic lesions that contribute to high pulmonary arterial pressure, like pulmonary vein stenosis. Heart-lung transplant procedures appear to have survival benefits over isolated lung transplantation in patients with pulmonary hypertension. Recurrence of pulmonary hypertension is rare after heart-lung transplant.

**DISORDERS OF THE SINUS NODE**

**Sinus Arrhythmia**

Phasic variation in the heart rate (sinus arrhythmia) is normal. Typically, the sinus rate varies with the respiratory cycle (heart rate increases with inspiration and decreases with expiration), whereas P-QRS-T intervals remain stable. Sinus arrhythmia may occur in association with respiratory distress or increased intracranial pressure, or it may be present in normal children. In isolation, it never requires treatment; however, it may be associated with sinus node dysfunction or autonomic nervous system dysfunction.

**Sinus Bradycardia**

Sinus bradycardia is defined as a heart rate below the normal limit for age (neonates to 6 years, 60 beats/min; 7–11 years, 45 beats/min; > 12 years, 40 beats/min). Sinus bradycardia is often seen in athletic children. Causes of sinus bradycardia include hypoxia, central nervous system damage, eating disorders, and medication side effects. Symptomatic bradycardia (syncope, low cardiac output, or exercise intolerance) requires treatment (atropine, isoproterenol, or cardiac pacing).

**Sinus Tachycardia**

The heart rate normally accelerates in response to stress such as exercise, anxiety, fever, hypovolemia, anemia, or HF. Although sinus tachycardia in the normal heart is well tolerated, symptomatic tachycardia with decreased cardiac output warrants evaluation for structural heart disease, hemodynamics and any operative procedures with surgical suture lines/scars place the patients at higher risk for certain types of arrhythmias.

The evaluation and treatment of cardiac rhythm disorders have advanced significantly over the last several decades. Arguably, the most significant advancements in the last few years have continued in the area of the genetic basis of rhythm disorders such as long QT syndrome which will be discussed at the end of the chapter. Treatment for cardiac rhythm abnormalities includes clinical monitoring with no intervention, antiarrhythmic medications, invasive electrophysiology study and ablation procedures, pacemakers, and internal cardioverter/defibrillators.
cardiomyopathy or true tachyarrhythmias. The first evaluation should be made with a 12-lead ECG to determine the precise mechanism of the rapid rate. Treatment may be indicated for correction of the underlying cause of sinus tachycardia (eg, transfusion for anemia or correction of hypovolemia or fever).

**Sinus Node Dysfunction**

Sinus node dysfunction is a clinical syndrome of inappropriate sinus nodal function and rate. The abnormality may be a true anatomic defect of the sinus node or its surrounding tissue, or it may be an abnormality of autonomic input. It is defined as one or more of the following: severe sinus bradycardia, marked sinus arrhythmia, sinus pause or arrest, chronotropic incompetence (inability of the heart rate to increase with activity or other demands), or combined bradyarrhythmias and tachyarrhythmias. It is usually associated with postoperative repair of congenital heart disease (most commonly the Mustard or Senning repair for complete TGA or the Fontan procedure), but it is also seen in normal hearts, in unoperated congenital heart disease, and in acquired heart diseases. Symptoms usually manifest between ages 2 and 17 years and consist of episodes of presyncope, syncope, palpitations, pallor, or exercise intolerance.

The evaluation of sinus node dysfunction may involve the following: baseline ECG, 24-hour ambulatory ECG monitoring, exercise stress test, and transient event monitoring. Treatment for sinus node dysfunction is indicated only in symptomatic patients. Bradyarrhythmias are treated with vagolytic (atropine) or adrenergic (aminophylline) agents or permanent cardiac pacemakers.

**PREMATURE BEATS**

**Atrial Premature Beats**

Atrial premature beats are triggered by an ectopic focus in the atrium. They are one of the most common premature beats occurring in pediatric patients, particularly during the fetal and newborn periods. The premature beat may be conducted to the ventricle and therefore followed by a QRS complex or it may be nonconducted, as the beat has occurred so early that the AV node is still refractory (Figure 20–4).
A brief pause usually occurs until the next normal sinus beat occurs. As an isolated finding, atrial premature beats are benign and require no treatment.

**Junctional Premature Beats**

Junctional premature beats arise in the atroventricular node or the bundle of His. They induce a normal QRS complex with no preceding P wave. Junctional premature beats are usually benign and require no specific therapy.

**Ventricular Premature Beats**

Ventricular premature beats are sometimes referred to as premature ventricular contractions (PVC) or as ventricular ectopy. They are relatively common, occurring in 1%–2% of patients with normal hearts. They are characterized by an early beat with a wide QRS complex, without a preceding P wave, and with a full compensatory pause following this early beat (Figure 20–5).

Ventricular premature beats originating from a single ectopic focus all have the same configuration; those of multifocal origin show varying configurations. The consecutive occurrence of two ventricular premature beats is referred to as a ventricular couplet and of three or more as ventricular tachycardia. Most ventricular premature beats in otherwise normal patients are usually benign. However, patients with frequent PVCs are usually evaluated further with tests such as a 24-hour ambulatory ECG or with exercise testing to rule out concerning arrhythmias. An echocardiogram may be performed to evaluate ventricular function. The significance of ventricular premature beats can be confirmed by having the patient exercise. As the heart rate increases, benign ventricular premature beats usually disappear. If exercise results in an increase or coupling of contractions, underlying disease may be present. Multifocal ventricular premature beats are always abnormal and may be more dangerous. They may be associated with drug overdose (tricyclic antidepressants or digoxin toxicity), electrolyte imbalance, myocarditis, or hypoxia. Treatment is directed at correcting the underlying disorder.

**SUPRAVENTRICULAR TACHYCARDIA**

Supraventricular tachycardia (SVT) is a term used to describe any rapid rhythm originating from the atrium, the atroventricular node, or an accessory pathway. These tachycardias are rapid, narrow complex tachycardias. The mode of presentation depends on the heart rate, the presence of underlying cardiac structural or functional abnormalities, coexisting illness, and patient age. An otherwise healthy child with SVT may complain of intermittent periods of rapid heartbeat. An infant with SVT may have poor feeding and increased fatigue (manifesting as less awake time). Incessant tachycardia, even if fairly slow (120–150 beats/min), may cause myocardial dysfunction and HF if left untreated. In children with preexisting HF or an underlying systemic disease such as anemia or sepsis, SVT may result in decreased heart function and further signs of hemodynamic instability much more rapidly than in a healthy child.

The mechanisms of tachycardia are generally divided into reentrant and automatic mechanisms and can be described by the location of tachycardia origination (Table 20–17).
Reentrant tachycardias represent approximately 80% of pediatric arrhythmias. Reentrant tachycardias have the following characteristics: they initiate abruptly, they have a fixed rate, they have little variation with fever or internal catecholamines, and they terminate abruptly. They can be terminated to sinus rhythm with maneuvers such as vagal maneuvers, administration of adenosine, pacing maneuvers, or DC cardioversion.

Reentrant tachycardia mechanisms involve two connections where electrical conduction travels down one of the pathways and then back up the other, creating a sustained repetitive circular loop. The circuit can be confined to the atrium (atrial flutter in a normal heart or intra-atrial reentrant tachycardia in a patient with congenital heart disease) (Figure 20–6). It may be confined within the AV node (AV nodal reentrant tachycardia), or it may encompass an accessory connection between atria and ventricle (accessory pathway–mediated tachycardia). If, during tachycardia, the electrical impulse travels antegrade (from atria to ventricles) through the AV node and retrograde (from ventricle to atria) back up the accessory pathway, orthodromic reciprocating tachycardia is present. If, instead, the impulse travels antegrade through the accessory pathway and retrograde up through the AV node, antidromic reciprocating tachycardia is present. This latter tachycardia would present as a wide complex tachycardia. Wolff-Parkinson-White (WPW) syndrome is a subclass of reentrant tachycardia in which, during sinus rhythm, the impulse travels antegrade down the accessory connection, bypassing the AV node and creating ventricular preexcitation (early eccentric activation of the ventricle with a short PR interval and slurred upstroke of the QRS, a delta wave) (Figure 20–7). Most patients with WPW have otherwise structurally normal hearts. However, WPW has been noted to occur with increased frequency in association with the following congenital cardiac lesions: tricuspid atresia, Ebstein anomaly of the tricuspid valve, HCM, and ccTGA. Different than other causes of tachycardias described above where the arrhythmia is not life-threatening, there have been rare cases of sudden collapse from WPW syndrome. The mechanism of this sudden event is the development of atrial fibrillation, conducting down a rapid accessory pathway to the ventricle leading to ventricular fibrillation and sudden death. For this reason, most centers recommend that even asymptomatic patients undergo an invasive procedure to assess the conduction properties of the WPW accessory pathway (described under treatment for tachyarrhythmias).

Improved surgical survival for patients with congenital heart disease has created a new, increasingly prevalent, chronic arrhythmia which is similar to atrial flutter in
a normal heart structure. These arrhythmias have been referred to by many names: intra-atrial reentrant tachycardia, incisional tachycardia, macroreentry, or postoperative atrial flutter. In this tachycardia, electrically isolated corridors of atrial myocardium (e.g., the tricuspid valve–inferior vena cava isthmus, or the region between an atrial incision and the crista terminalis) act as pathways for sustained reentrant circuits of electrical activity. These tachycardias are chronic, medically refractory, and clinically incapacitating.

The automatic tachycardias represent approximately 20% of childhood arrhythmias. The characteristics of these types of arrhythmias include gradual onset, rate variability, variations in rate with fever or increasing internal catecholamines, and gradual offset. Maneuvers such as vagal maneuvers, adenosine, and attempt pacing can alter the rhythm temporarily but they do not result in termination of the rhythm to sinus rhythm as would be seen in the reentrant tachycardias. Automatic tachycardias can be episodic or incessant. They are usually under autonomic influence. When they are incessant, they are usually associated with HF and a clinical picture of DCM. Automatic tachycardias are created when a focus of cardiac tissue develops an abnormally fast spontaneous rate of depolarization. For ectopic atrial tachycardia, the ECG demonstrates a normal QRS complex preceded by an abnormal P wave (Figure 20–8). Junctional ectopic tachycardia does not have a P wave preceding the QRS waves and may be associated with AV dissociation or 1:1 retrograde conduction.

Clinical Findings

A. Symptoms and Signs

Presentation varies with age. Infants tend to turn pale and mottled with onset of tachycardia and may become irritable. With long duration of tachycardia, symptoms of HF develop. Older children complain of dizziness, palpitations, fatigue, and chest pain. Heart rates range from 240–300 beats/min in the younger child to 150–180 beats/min in the teenager. HF is less common in children than in infants. Tachycardia may be associated with either congenital heart defects or acquired conditions such as cardiomyopathies and myocarditis.

B. Imaging

Chest radiographs are normal during the early course of tachycardia and therefore are usually not obtained. If HF is present, the heart is enlarged and pulmonary venous congestion is evident.

C. Electrocardiography

ECG is the most important tool in the diagnosis of SVT and to define the precise tachycardia mechanism. Findings include a heart rate that is rapid and out of proportion to the patient’s physical status (eg, a rate of 140 beats/min with an abnormal P wave while quiet and asleep). For reentrant mechanisms, the rhythm would be extremely regular with little variability. For automatic mechanisms, the rhythm would be irregular with a gradual increasing and decreasing of the rate. The QRS complex is usually the same as during normal sinus rhythm. However, the QRS complex is occasionally widened (SVT with aberrant ventricular conduction), in which case the condition may be difficult to differentiate from ventricular tachycardia. The presence of P waves and their association with the QRS are important in determining tachycardia mechanism. With automatic tachycardias, there is often a 1:1 or 2:1 A:V relationship with P waves preceding the QRS. With reentrant tachycardias, such as accessory pathway-mediated tachycardias, a small retrograde P wave can often be seen just after the QRS. With atrioventricular nodal reentrant tachycardia, P waves cannot be identified as they are occurring at the same time as the QRS.

Treatment

A. Acute Treatment

During the initial episodes of SVT, patients require close monitoring. Correction of acidosis and electrolyte abnormalities is also indicated. The following acute treatments are effective in terminating tachycardia only for patients with reentrant SVT. Acute treatment for automatic SVT is aimed at rate control, usually with a β-blocker.

1. Vagal maneuvers—The “diving reflex” produced by placing an ice bag on the nasal bridge for 20 seconds (for infants) will increase parasympathetic tone and terminate some tachycardias. The Valsalva maneuver, which can be performed by older compliant children, may also terminate reentrant tachycardias.

2. Adenosine—Adenosine transiently blocks AV conduction and terminates tachycardias that incorporate the AV node or may aid in the diagnosis of arrhythmias confined to the atrium by causing a pause in ventricular conduction, so one can identify the presence of multiple P waves. The dose is 100–250 mcg/kg by rapid intravenous bolus. It is antagonized by aminophylline and should be used with caution in patients with sinus node dysfunction or asthma.

3. Transesophageal atrial pacing—Atrial overdrive pacing and termination can be performed from a bipolar electrode-tipped catheter positioned in the esophagus adjacent to the left atrium. Overdrive pacing at rates approximately 30% faster than the tachycardia rate will interrupt a reentrant tachycardia circuit and restore sinus rhythm.

4. Direct current cardioversion—Direct current cardioversion (0.5–2 synchronized J/kg) should be used immediately when a patient presents in cardiovascular collapse. This will convert a reentrant mechanism to sinus. Automatic tachycardia will not respond to cardioversion.

B. Chronic Treatment

Once the patient has been diagnosed with SVT and the mechanism has been evaluated, then long-term treatment options can be considered. Options include monitoring clinically for tachycardia recurrences, medical management with antiarrhythmic medications, or an invasive electrophysiology study and ablation procedure. In infancy and early childhood, antiarrhythmic medications are the mainstay of therapy. Medications such as digoxin and β-blockers are the first-line therapies. Other antiarrhythmic medications (eg, verapamil, flecainide, propafenone, sotalol, and amiodarone) have increased pharmacologic actions and are extremely effective. However, these medications also have serious side effects, including induction of arrhythmias and sudden death, and should be used only under the direction of a pediatric cardiologist.

Tachycardias, both automatic and reentrant, can be more definitively addressed with an invasive electrophysiology study and ablation procedure. This is a nonsurgical transvascular catheter technique that desiccates an arrhythmia focus or accessory pathway and permanently cures an arrhythmia. The ablation catheters can utilize either a heat source (radiofrequency) or a cool source (cryoablation). The latter has been reported to be safer around the normal conduction pathway and thus decreases the risk of inadvertent atrioventricular block. The success rate from an ablation procedure in a patient with a normal heart structure is > 90%, with a
recurrence risk of < 10%. The procedure can be performed in infants or adults. In children younger than age 4 years, the risks of procedural complications or failed ablation are potentially higher, and the procedure should be reserved for those whose arrhythmias are refractory to medical management. The high success rate, low complication and low recurrence rates, in addition to the elimination of the need for chronic antiarrhythmic medications have made ablation procedures the primary treatment option in most pediatric cardiovascular centers. In patients with congenital heart disease, electrophysiology study and ablation procedures are also utilized to address arrhythmia substrates. The success rate of these procedures is lower in patients with a normal heart structure, often reported in the 75%–80% range.

**Prognosis**

SVT in infants and children generally carries an excellent prognosis. It can be treated with medical management or with the potentially curative ablation procedures. There are, however, rare cases of incessant SVT leading to HF and there is reported sudden collapse from atrial fibrillation in the presence of WPW. All patients with complaints of rapid heartbeats or other symptoms where there is a concern for tachyarrhythmia should be referred for evaluation.

**VENTRICULAR TACHYCARDIA**

Ventricular tachycardia is uncommon in childhood (Figure 20–9). It is usually associated with underlying abnormalities of the myocardium (myocarditis, cardiomyopathy, myocardial tumors, or postoperative congenital heart disease) or toxicity (hypoxia, electrolyte imbalance, or drug toxicity). On occasion, it can be secondary to a primary electrical abnormality in an otherwise normal heart. Sustained ventricular tachycardia can be an unstable situation, and, if left untreated, it could degenerate into ventricular fibrillation and sudden collapse.

Ventricular tachycardia must be differentiated from accelerated idioventricular rhythm. The latter is a sustained ventricular tachycardia occurring in neonates with normal hearts, with a ventricular tachycardia rate within 10% of the preceding sinus rate. This is a self-limiting arrhythmia that requires no treatment. Because of the consequences of sustained ventricular tachycardia, however, a symptomatic patient with a wide complex tachycardia should be considered to have ventricular tachycardia (not an accelerated idioventricular rhythm) until proven otherwise.

Acute termination of ventricular tachycardia involves restoration of the normal myocardium when possible (correction of electrolyte imbalance, drug toxicity, etc) and direct current cardioversion (1–4 J/kg), cardioversion with lidocaine (1 mg/kg), or with amiodarone (5 mg/kg load). Chronic suppression of ventricular arrhythmias with antiarrhythmic drugs has many side effects (including proarrhythmia and death), and it must be initiated in the hospital under the direction of a pediatric cardiologist. If the etiology of the tachycardia is a primary electrical abnormality, then catheter ablation procedures can be offered in select patients as a potentially curative treatment option. Ablation for ventricular tachycardia in the pediatric population is much less commonly performed compared to ablation for SVT.

▲ Figure 20–9. Twelve-lead ECG from a child with imipramine toxicity and ventricular tachycardia.
LONG QT SYNDROME

Long QT syndrome is a malignant disorder of cardiac conduction where cardiac repolarization is prolonged (QTc measurement on ECG) and this predisposes the patient to sudden episodes of syncope, seizures, or sudden death (5% per year if untreated). The mechanism is a pause-dependent initiation of torsades de pointes, a multifocal ventricular tachycardia. It can be congenital or acquired. Congenital long QT syndrome is inherited in an autosomal dominant (more common) or recessive pattern or it may occur spontaneously (less likely). The recessive inheritance pattern is associated with congenital deafness and the Jervell and Lange-Nielsen syndrome. Congenital long QT syndrome is caused by a defect in one of several genes that code for ion channels in cardiac myocytes. As many as 10 genes have been identified and these defects explain 75% of the patient population with symptoms and signs consistent with long QT. The diagnosis of long QT syndrome is suspected in a patient or a family with a history of sudden syncope, seizures, documented dysrhythmia, or cardiac arrest. Evaluation includes an ECG which shows a long QTc measurement, 24-hour ambulatory ECG, and possibly an exercise test. There is a commercially available genetic test for the primary genes which cause long QT syndrome. This test is most helpful in determining who in a family has long QT syndrome. Unfortunately, this test cannot completely rule it out as there continues to be a 25% false negative rate.

The mainstay of treatment for long QT syndrome has been exercise restriction, treatment with β-blockade, and possibly the placement of an internal cardioverter/defibrillator. Within the next several years, more gene-specific therapies are anticipated to be developed.

Long QT syndrome can also be acquired, resulting from altered ventricular repolarization secondary to myocardial toxins, ischemia, or inflammation. This condition also predisposes a patient to ventricular arrhythmias. Numerous medications can also cause QT prolongation.

SUDDEN DEATH

Long QT syndrome and HCM are two of the most common cause of sudden death in young athletes. Other causes include dilated or restrictive cardiomyopathies, arrhythmogenic RV dysplasia, congenital structural anomalies of the coronary arteries, and primary arrhythmias such as catecholaminergic ventricular tachycardia or Brugada syndrome. Many of these causes are genetic and thus it is necessary to conduct a detailed family history looking for seizures, syncope, or early sudden death. Family members should be examined with an arrhythmia screen consisting of a physical examination, ECG, and echocardiography to detect arrhythmias or cardiomyopathies. Arrhythmias in patients with postoperative congenital heart disease are important causes of morbidity and mortality and may present as sudden death events.

DISORDERS OF ATRIOVENTRICULAR CONDUCTION

General Considerations

The atrioventricular node is the electrical connection between the atrium and the ventricles. Atrioventricular blocks involve a slowing or disruption of this connection and are described according to the degree of this slowing or disruption.

First-Degree Atrioventricular Block

First-degree atrioventricular block is an ECG diagnosis of prolongation of the PR interval. The block does not, in itself, cause problems. It may be associated with structural congenital heart defects, namely AV septal defects and ccTGA, and with diseases such as rheumatic carditis. The PR interval is prolonged in patients receiving digoxin therapy.

Second-Degree Atrioventricular Block

Mobitz type I (Wenckebach) atrioventricular block is recognized by progressive prolongation of the PR interval until there is no QRS following a P wave (Figure 20–10). Mobitz type I block occurs in normal hearts at rest and is usually benign. In Mobitz type II block, there is no progressive lengthening of the PR interval before the dropped beat (Figure 20–11). Mobitz type II block is frequently associated
with organic heart disease, and a complete evaluation is necessary.

**Complete Atrioventricular Block**

In complete atrioventricular block, the atria and ventricles beat independently. Ventricular rates can range from 40 to 80 beats/min, whereas atrial rates are faster (Figure 20–12). The most common form of complete atrioventricular block is congenital complete atrioventricular block which occurs in a fetus or infant with an otherwise normal heart. There is a very high association with maternal systemic lupus erythematosus antibodies and therefore it is recommended to screen the mother of an affected infant even if the mother has no symptoms of collagen vascular disease. Congenital complete atrioventricular block is also associated with some forms of congenital heart disease (congenitally corrected transposition of the great vessels and AV septal defect). Acquired complete atrioventricular block may be secondary to acute myocarditis, drug toxicity, electrolyte imbalance, hypoxia, and cardiac surgery.

**Clinical Findings**

The primary finding in infants and children with complete atrioventricular block is a significantly low heart rate for age. The diagnosis is often made prenatally when fetal bradycardia is documented. An ultrasound is then conducted as well as a fetal echocardiogram of the heart. With the fetal echocardiogram, atrial and ventricular contractions can be distinguished and the atrial rate is documented as being higher than the ventricular rate with no relationship to each other. If the heart rates are sufficiently low, then there will be low cardiac output, decreased cardiac function, and the development of hydrops fetalis. Postnatal adaptation largely depends on the heart rate; infants with heart rates less than 55 beats/min are at significantly greater risk for low cardiac output, HF, and death. Wide QRS complexes and a rapid
atrial rate are also poor prognostic signs. Most patients have an innocent flow murmur from increased stroke volume. In symptomatic patients, the heart can be quite enlarged, and pulmonary edema may be present.

Complete atrioventricular block can also occur in older patients. Patients may be asymptomatic or may present with presyncope, syncope, or fatigue. Complete cardiac evaluation, including ECG, echocardiography, and Holter monitoring, is necessary to assess the patient for ventricular dysfunction and to relate any symptoms to concurrent arrhythmias.

**Treatment**

When diagnosis of complete atrioventricular block is made in a fetus, the treatment depends on gestational age, ventricular rate, and the presence or absence of hydrops. Some centers have advocated the administration of steroids, intravenous immune globulin (IVIG), and/or β-adrenergic stimulation treatment of the mother in some instances (fetuses that have associated heart failure). Emergent delivery is sometimes warranted. Postnatal treatment for neonates or older patients who present with significant symptoms and require immediate intervention includes temporary support by the infusions of isoproterenol, temporary transvenous pacing wires, or by temporary transcutaneous pacemakers if needed. The relationship of complete congenital atrioventricular block to auto-antibody production and cardiomyopathy is the basis for the consideration of immune modulation with steroids and IVIG in neonates in addition to their mothers. Long-term treatment involves the placement of a permanent pacemaker.

**SYNCOPE (FAINTING)**

**INTRODUCTION**

Syncope is defined as the transient loss of consciousness and postural tone resulting from an abrupt, temporary decrease in cerebral blood flow. It is one of the most common referrals to pediatric cardiology. There is an estimated 30% lifetime risk. The majority of episodes are self-limited and benign and are known as vasovagal syncope or “simple fainting.” It is a disorder of heart rate and blood pressure control by the autonomic nervous system that causes hypotension or bradycardia. Rarely, syncope can be the first warning sign of a serious condition such as arrhythmia, structural heart disease, or non-cardiac disease. Even vasovagal syncope, if recurrent, can cause a major impact on lifestyle, interfering with school and/or sports. Many states impose driving

**Figure 20-12.** Twelve-lead ECG and lead II rhythm strip of complete heart block. The atrial rate is 150 beats/min, and the ventricular rate is 60 beats/min.
restrictions following syncope. Therefore, accurate diagnosis and counseling are important.

**DIAGNOSTIC EVALUATION**

Given the many possible causes of syncope, a carefully planned approach is preferred to avoid an involved and expensive diagnostic evaluation. The patient history, family history, physical examination, and an electrocardiogram are fundamental and direct the remainder of the evaluation. Important historical details include the age of the patient (syncope is rare before 10 years of age except for breathing holding syncope), time of day (early morning is typical), the state of hydration and nutrition at the time of the event (last fluid or food intake), the environmental conditions (ambient temperature), the patient’s activity or body position immediately prior to the syncope episode, the frequency and duration of the episodes, and any aura, prodrome, or specific symptoms prior to the episode. Witnesses should provide details regarding the patient’s condition prior to syncope, duration of loss of consciousness, any injuries or seizure-like movements, loss of bowel or bladder function, heart rate during episode, and duration and nature of recovery. Medication history (prescription and over the counter supplements) is critical and may point to proarrhythmic potential. Additionally, a history of severe viral illness such as infectious mononucleosis frequently precedes the development of vasovagal syncope. Pertinent positives of the past medical history include neurological disorders, traumatic brain injury, and neurosurgical interventions.

It is not uncommon to elicit a history of multiple family members who experienced syncope during adolescence that subsequently resolved. However, if the family history is positive for recurrent syncope, it is also important to consider familial disorders and question about the presence of hypertrophic or dilated cardiomyopathy, long QT syndrome, Brugada Syndrome, exertional syncope (to consider catecholaminergic polymorphic ventricular tachycardia), primary pulmonary hypertension, or arrhythmogenic right ventricular cardiomyopathy. Additionally, families should be asked about sudden unexplained death in children or young adults (drownings, single car accidents, sudden cardiac death, and SIDS), seizures, and congenital deafness. A genetic counselor can frequently be helpful in organizing the family history.

On physical examination, the general condition should be noted, with particular emphasis on hydration, nutritional status (evidence of eating disorders), and manifestations of thyroid disease. Orthostatic vital signs should be obtained, but care must be taken to follow a strict protocol to avoid false positives. Orthostatic hypotension is defined as a decrease in systolic blood pressure of 20 mm Hg or a decrease in diastolic blood pressure of 10 mm Hg after three minutes of standing when compared with blood pressure in the supine or sitting position. Pulse strength, rate, and any differences between upper and lower extremities should be noted. The presence of heart murmurs suggesting anatomic disease should prompt an echocardiogram. Finally, a phenotype of inherited connective tissue disorders (ie, Marfan Syndrome) should be considered.

An EKG should be obtained, particularly if syncope is recurrent or occurs with exercise. It should be evaluated for heart rate, corrected QT interval, T-wave abnormalities (including T-wave alternans), or any ventricular arrhythmias, as well as for ventricular pre-excitation, atrioventricular (AV) conduction disturbances, or features consistent with Brugada Syndrome. All patients with exertional syncope, even those with positive orthostatic vital signs, should undergo additional evaluation with an echocardiogram and exercise stress testing. Echocardiograms are necessary to examine for cardiomyopathy, myocarditis, anomalous coronary arteries, pulmonary arterial hypertension, and arrhythmogenic right ventricular cardiomyopathy. An exercise test is necessary for catecholaminergic polymorphic ventricular tachycardia. Additionally testing may include a signal averaged EKG, Holter monitor, MRI, cardiac catheterization, and invasive electrophysiological testing. Tilt table testing is less commonly performed in pediatric patients as the diagnosis of vasovagal syncope does not require a positive tilt test and results of unclear significance (ie, prolonged asystolic pauses) are common.

**VASOVAGAL/NEUROCARDIOGENIC SYNCOPE**

**Pathophysiology/Clinical Presentation**

By far the most common etiology for syncope in pediatrics is vasovagal or neurocardiogenic syncope. While the pathophysiologic mechanisms are heterogenous and not completely understood, it is thought to be primarily a response of the cardiac-central nervous system reflex. The most common initiating event is prolonged or rapid assumption of an upright position which results in gravitationally mediated venous pooling in the lower extremities. This causes central hypovolemia leading to decreased venous return and stroke volume. Alternatively, an emotional or physical stress (pain or fright) or a reflex mechanism related to hair grooming, glutation (swallowing), or micturition can trigger this sequence by creating a sympathetic response characterized by tachycardia and vasoconstriction. This increased sympathetic output may result in a subsequent parasympathetic response characterized by bradycardia or asystole. Additionally, the abrupt withdrawal of sympathetically mediated tachycardia despite persistent peripheral vasodilation causes a decrease in systemic blood pressure and venous return/ stroke volume.

As a result of loss of consciousness, the patient falls into a supine state which restores venous return and central
blood volume. The loss of consciousness is short (< 1–2 min), with rapid return to baseline behavior. Bowel or bladder incontinence is uncommon and, although seizures rarely occur, myoclonic “jerks” are common. A prodrome consisting of nausea, epigastric pain, clammy sensation, pallor, dizziness, lightheadedness, tunnel vision, and weakness is very characteristic of vasovagal or neurocardiogenic syncope. Some patients with profound bradycardia or asystole may have little to no warning and will typically require additional evaluation to confirm the diagnosis. If the prodrome is of sufficient duration, patients may learn to recognize it and lie down to prevent complete loss of consciousness.

**Therapy**

Maintaining adequate intravascular volume is the mainstay of treatment of vasovagal syncope. While choosing a fluid volume goal is acceptable, having patients target clear urine at least five times per day ensures appropriate intake. Increased salt intake with salt tablets or simply increased dietary sources (a handful of salted peanuts or crackers) is also recommended. Counter regulatory maneuvers such as leg pumping, leg crossing, and squatting can ameliorate the presyncopal symptoms and frequently avoid complete loss of consciousness. Finally, regular aerobic exercise should be encouraged as it strengthens the muscles of the lower extremities and improves vascular tone. Medications can be useful although these frequently rely on adequate hydration for effectiveness.

There are only limited randomized studies of medications in pediatric patients. Fludrocortisone is a mineralocorticoid that results in renal salt resorption and thus increases intravascular volume. Alpha agonist agents such as midodrine work through their vasoconstrictor effects. Their utility is limited by the necessity for three times daily administration. Although β-blockers have been used for treatment of syncope by targeting the increased sympathetic output with resultant parasympathetic response, the side effects may mask the therapeutic benefits and there is a paucity of data regarding their effectiveness. Vagolytic agents (disopyramide) help control hyperventilation, and the selective serotonin reuptake inhibitors have also been effective in alleviating symptoms in select patients.

Gastroesophageal Reflux & GERD

Key definitions:

- **Gastroesophageal reflux (GER)** refers to uncomplicated recurrent spitting and vomiting in healthy infants that resolves spontaneously.
- **Gastroesophageal reflux disease (GERD)** is present when reflux causes secondary symptoms or complications.
- **Esophageal manifestations of GERD** include symptoms (heartburn, regurgitation) and mucosal complications (esophagitis, stricture, Barrett esophagus) primarily related to acid exposure in the upper gastrointestinal (GI) tract, primarily the esophagus itself.
- **Extraesophageal manifestations of GERD** include a myriad of clinical disorders that may be linked to reflux, including upper and lower airway symptoms and findings, as well as dental erosions. In most settings, objective confirmation of extraesophageal reflux complications is challenging.

Clinical Findings

A. Infants With Gastroesophageal Reflux

Gastroesophageal (GE) reflux is common in young infants and is a physiological event. Frequent postprandial regurgitation, ranging from effortless to forceful, is the most common infant symptom. Infant GER is usually benign, and it is expected to resolve by 12–18 months of life.

Reflux of gastric contents into the esophagus occurs during spontaneous relaxations of the lower esophageal sphincter that are unaccompanied by swallowing. Factors promoting reflux in infants include small stomach capacity, frequent large-volume feedings, short esophageal length, supine positioning, and slow swallowing response to the flow of refluxed material up the esophagus. Infants’ individual responses to the stimulus of reflux, particularly the maturity of their self-settling skills, are important factors determining the severity of reflux-related symptoms.

When infants develop symptoms such as failure to thrive, food refusal, pain behavior, GI bleeding, upper or lower airway-associated respiratory symptoms, or Sandifer syndrome, these indicate gastroesophageal reflux disease (GERD).

B. Older Children With Reflux

Older children with GERD complain of adult-type symptoms such as regurgitation into the mouth, heartburn, and dysphagia. Esophagitis can occur as a complication of GERD and requires endoscopy with biopsy for diagnostic confirmation. Children with asthma, cystic fibrosis, developmental handicaps, hiatal hernia (HH), and repaired tracheoesophageal fistula are at increased risk of GERD and esophagitis.

C. Extraesophageal Manifestations of Reflux Disease

GERD is implicated in the pathogenesis of several disorders unrelated to esophageal dysfunction. In infants, GERD has been linked to the occurrence of apnea or apparent life-threatening events (ALTEs), although the majority of pathologic cases are not reflux associated. Upper airway symptoms (hoarseness, sinusitis, laryngeal erythema, and edema),
lower airway symptoms (asthma, recurrent pneumonia, recurrent cough), dental erosions, and Sandifer syndrome have all been linked to GERD, although proof of cause-and-effect relationship is challenging.

D. Diagnostic Studies

History and physical examination alone should help differentiate infants with benign, recurrent vomiting (physiologic GER) from those who have red flags for GERD or other underlying primary conditions that may present with recurrent emesis at this age. Warning signs that warrant further investigation in the infant with recurrent vomiting include bile-stained emesis (a warning sign for intestinal obstruction), GI bleeding, onset of vomiting after 6 months, failure to thrive, diarrhea, fever, hepatosplenomegaly, abdominal tenderness or distension, or neurologic changes.

An upper GI series should be considered when anatomic etiologies of recurrent vomiting are considered, but should not be considered to be a test for GERD.

In older children with heartburn or frequent regurgitation, a trial of acid-suppressant therapy may be both diagnostic and therapeutic. If a child has symptoms requiring ongoing acid suppressant therapy, or if symptoms fail to improve with empiric therapy, consider referral to a pediatric gastroenterologist to assist in evaluation for complicated GERD, or nonreflux diagnoses including eosinophilic esophagitis (EoE).

Esophagoscopy and mucosal biopsies are useful to evaluate for mucosal injury secondary to GERD (Barrett esophagus, stricture, erosive esophagitis), or to evaluate for nonreflux diagnoses that present with reflux-like symptoms, including EoE. Endoscopic evaluation is not requisite for the evaluation of all infants and children with suspected GERD.

Intraluminal esophageal pH monitoring (pH probe) and combined multiple intraluminal impedance and pH monitoring (pH impedance probe) are indicated to quantify reflux, and to evaluate for objective evidence of symptom associations with regards to atypical reflux presentations. pH probe studies quantify esophageal acid exposure, and pH impedance studies also add detection of bolus fluid transit, including both acidic and nonacidic reflux. pH impedance studies in particular may have higher diagnostic yield in evaluating for respiratory or atypical complications of reflux disease, or in evaluating for breakthrough reflux symptoms while a patient is on acid-suppressant therapy.

Treatment & Prognosis

Reflux resolves spontaneously in 85% of affected infants by 12 months of age, coincident with assumption of erect posture and initiation of solid feedings. Until then, regurgitation volume may be reduced by offering small feedings at frequent intervals and by thickening feedings with rice cereal (2–3 tsp/oz of formula). In infants with unexplained crying/fussy behavior, no evidence supports empiric use of acid suppression.

Acid suppression may be used to treat suspected esophageal or extraesophageal complications of acid reflux in infants and older children. Therapeutic options include histamine-2 (H$_2$)–receptor antagonists or proton pump inhibitors (PPIs). PPI therapy has been shown to significantly heal both esophageal mucosal injury and symptoms from GERD within an 8–to 12-week period. Potential risk factors associated with long-term PPI therapy include risk for infection (pneumonia, Clostridium difficile–associated diarrhea), and an increased risk for osteoporosis has been demonstrated in adults. Although there are no standardized recommendations regarding prophylaxis or surveillance for these complications in pediatric patients on long-term PPI therapy, one should consider weaning or discontinuing treatment if it is no longer required. There is no sufficient evidence to support the routine use of prokinetic agents for treatment of pediatric GERD.

Spontaneous resolution is less likely in older children with GERD and those with underlying neurodevelopmental disorders. Episodic symptoms may be controlled with intermittent use of acid blockers. Patients with persistent symptoms may require chronic acid suppression. Complications of reflux esophagitis or chronic GERD include feeding dysfunction, esophageal stricture, and anemia (Figure 21–1). Barrett esophagus, a precancerous condition, is very uncommon in children, but it may occur in patients with an underlying primary diagnosis that offers high risk for GERD.

Figure 21–1. Esophagitis associated with gastroesophageal reflux disease. Mucosa is erythematous with loss of vascular pattern.
Antireflux surgery (Nissen fundoplication) may be considered in a child with GERD who (1) fails medical therapy (2) is dependent on persistent, aggressive medical therapy, (3) is nonadherent to medical therapy, and (4) has persistent, severe respiratory complications of GERD or other life-threatening complications of GERD. Potential complications after antireflux surgery include dumping syndrome, gas bloat syndrome, persistent retching/gagging, or wrap failure.

**EOSINOPHILIC ESOPHAGITIS**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

► Feeding dysfunction, dysphagia, esophageal food impaction, and heartburn.
► Must rule out other causes for esophageal eosinophilia before assigning diagnosis of eosinophilic esophagitis (EoE).
► Esophageal food impaction and esophageal stricture are two most common complications.
► Elimination of food allergens or swallowed topical steroids are effective treatments for EoE.

**Clinical Findings**

**A. Symptoms and Signs**

This recently recognized entity occurs in all ages and more frequently affects boys. Common initial presentations in young children include feeding dysfunction and vague nonspecific symptoms of GERD such as abdominal pain, vomiting, and regurgitation. If a history of careful and lengthy chewing, long mealtimes, washing food down with liquid or avoiding highly textured foods is encountered, one may suspect EoE. In adolescent’s symptoms of solid food dysphagia, and acute and recurrent food impactions predominate. If a child’s symptoms are unresponsive to medical and/or surgical management of GERD, EoE should be strongly considered as a diagnostic possibility. A family or personal history of atopy, asthma, dysphagia, esophageal dilation or food impaction is often present.

**B. Laboratory Findings**

Peripheral eosinophilia may or may not be present. The esophageal mucosa usually appears abnormal with features of thickening, mucosal fissures, strictures, and rings. The esophagus is often sprinkled with pinpoint white exudates that superficially resemble Candida infection. On microscopic examination the white spots are composed of eosinophils (Figure 21–2). A lengthy stricture can be seen at the time of endoscopy but esophagrams may capture this more often. If a proximal stricture is identified, EoE should be strongly considered as a diagnostic possibility for symptoms. Serum IgE may be elevated, but this is not a diagnostic finding. Specific allergens can often be identified by skin testing, and patient can sometimes identify foods that precipitate pain and dysphagia.

**Diagnosis**

The diagnosis of EoE is based on both clinical and histopathological features. Symptoms referable to esophageal

![Figure 21–2. Esophagitis associated with eosinophilic esophagitis. Mucosa contains linear folds, white exudate, and has loss of vascular pattern.](Image)
dysfunction must be seen in association with esophageal eosinophilia and a normal gastric and duodenal mucosa. Other causes for esophageal eosinophilia, in particular, GERD, must be ruled out.

**Treatment**

Dietary exclusion of offending allergens (elemental diet, removal of allergenic foods) is effective treatment, but adherence in older children can be difficult. Topical corticosteroids are an effective treatment. Steroids are puffed in the mouth and swallowed from a metered dose pulmonary inhaler; this method of administration is completely opposite of how topical steroids are administered for the treatment of asthma. Two puffs of fluticasone from an inhaler twice daily is a common recommendation. Patients should not rinse their mouth or eat for 30 minutes to maximize the effectiveness. Esophageal dilation may be required to treat strictures. The association of EoE and esophageal malignancy has not been identified. Parent and family support is available at American Partnership for Eosinophilic Disorders APFED.org.

ACHALASIA OF THE ESOPHAGUS

**A. Symptoms and Signs**

Achalasia occurs rarely in pediatrics, with an incidence of 0.11 per 100,000 and most commonly in children who are older than 5 years. Cases during infancy have been reported, but overall less than 5% of achalasia occurs in patients less than 15 years of age. Common symptoms reported were emesis (84.6%), dysphagia (69.2%), weight loss (46.0%), and chronic cough (46.1%). Patients may eat slowly and often require large amounts of fluid when ingesting solid food. Familial cases occur in Allgrove syndrome (alacrima, adrenal insufficiency, and achalasia, associated with a defect in the AAAS gene on 12q13, encoding the ALADIN protein) and familial dysautonomia. There have been recent case reports of achalasia in pediatric autism patients and a defect in the HLA-DQb1 gene has been associated with increased risk in European populations.

B. Imaging and Manometry

Barium esophagram shows a dilated esophagus with a tapered “beak” at the GE junction. Fluoroscopy shows irregular tertiary contractions of the esophageal wall, indicative of disordered esophageal peristalsis. Achalasia has also been identified incidentally in patients undergoing GE scintigraphy. Esophageal manometry classically shows high resting pressure of the lower esophageal sphincter, failure of sphincter relaxation after swallowing, and abnormal esophageal peristalsis, though these findings may be sporadic, with partial or normal relaxations present in some swallows. Examination of high-resolution manometry in pediatric achalasia has shown high inter and intra-rater reliability using standardized software diagnosis packages.

C. Differential Diagnosis

Congenital or peptic stricture, webs, and masses of the esophagus may mimic achalasia. EoE commonly presents with symptoms of dysphagia and food impaction, similar to achalasia. Cricopharyngeal achalasia or spasm is a rare cause of dysphagia in children, but it shares some clinical features of primary achalasia of the LES. Intestinal pseudo-obstruction, multiple endocrine neoplasia type 2b, systemic amyloidosis, and post-vagotomy syndrome cause esophageal dysmotility similar to achalasia. Teenage girls may be suspected of having an eating disorder. In Chagas disease, caused by the parasite *Trypanosoma cruzi*, nNOS and ganglion cells are diminished or absent in the muscular layers of the LES causing an acquired achalasia.

**Treatment & Prognosis**

Endoscopic injection of botulinum toxin paralyzes the lower esophageal sphincter and temporarily relieves obstruction but up to 85% patients may ultimately require myotomy. Pneumatic dilation trials in children are limited, but a recent single center experience of endoscopic dilation showed a long-term success rate of up to 87% with one to three dilations. Because of concerns that dilation may increase inflammation between the esophageal mucosal and muscular layers, however, some have advocated surgical (Heller) myotomy as the best initial treatment. Recent meta-analysis of 21 studies of myotomy outcomes encompassing 331 children showed a general response rate of 85%, with 7% requiring surgical revision and a 9% perforation rate. Postoperative GERD is common, and in the meta-analysis fundoplication was performed in 82% cases, though rates of postoperative GERD was not significantly different between those with and without fundoplication. In a large retrospective pediatric study, general response rates of pneumatic dilation compared to Heller myotomy were not significantly different, though some suggest that children older than 6 years may have better outcomes with pneumatic dilation. Other small
CAUSTIC BURNS OF THE ESOPHAGUS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Reported history of ingestion, with or without evidence of oropharyngeal injury.
- Odynophagia, drooling, and food refusal typical of esophageal injury.
- Endoscopic evaluation of severity and extent of injury at 24–48 hours postingestion.
- Significant risk for development of esophageal strictures, especially in second- and third-degree lesions.

Clinical Findings

A. Symptoms and Signs

Ingestion of caustic solids or liquids (pH < 2 or pH > 12) produces esophageal lesions ranging from superficial inflammation to deep necrosis with ulceration, perforation, mediastinitis, or peritonitis. A recent meta-analysis encompassing more than 11,000 ingestions indicates a slight male predominance and a mean age of ingestion of 2.78 years. Acidic substances typically have a sour taste and therefore lead to limited injury because of the small volume ingested. Their pathogenesis is due to superficial coagulative necrosis with eschar formation. Conversely, the more benign taste of alkali ingestions may allow for larger volume ingestions and subsequent liquifactive necrosis that can lead to deeper mucosal penetration. Overall, acidic ingestions account for 31% and alkaline ingestions for 42% of caustic ingestions. Additional factors that determine the severity of injury include the amount ingested, the physical state of the agent, and the duration of mucosal exposure time, making powdered or gel formulations of dishwashing detergent especially dangerous. Ingestions of liquid detergent capsules or pods have become the most common form of household product ingestion, due in part to their bright coloring and benign taste. They tend to cause more respiratory than esophageal injury, however. The lips, mouth, and airway should be examined in suspected caustic ingestion, although up to 12% of children without oral lesions can have significant esophageal injury.

B. Imaging Studies

Esophagoscopy is often performed; however, timing is important as endoscopy may not indicate the true severity of injury if it is performed too early (< 24–48 hours) and may increase the risk of perforation if it is performed too late (> 72 hours) due to formation of granulation tissue. Grading of esophageal lesions into first degree (superficial injury, erythema only), second degree (transmural with circumferential sloughing and deep mucosal ulceration) can help predict prognosis. Circumferential lesions carry the highest risk of stricture formation. In a recent large single-center study, 34% of ingestions in children were grade 2 or 3, with 50% of these requiring one or more endoscopic dilations. If dilation is felt to be necessary, it should not be performed in the acute phase of injury, though a recent study showed that early initiation of dilations by 15 days decreased the duration and number of dilations ultimately needed. Elevation of white blood cell count was found to be a sensitive, but not specific, indicator of high-grade injury. In addition, even without clinical findings, endoscopic esophageal lesions have been found in up to 35% and gastric lesions in up to 14% of patients. Plain radiographs of the chest and abdomen may be performed if there is clinical suspicion of perforation. Contrast studies of the esophagus should be performed when endoscopic evaluation is not available, though they are unlikely to detect grades 1 and 2 lesions. Some centers have advocated conservative management with upper GI series within 3 weeks
of injury, reserving endoscopic evaluation for those with evidence of stricture. CT scan has been proposed as a less invasive option than endoscopy for injury assessment, but results have proven less reliable.

> Treatment & Prognosis

Clinical observation is always prudent, as it is often difficult to predict the severity of esophageal injury at presentation. A large study of almost 1000 pediatric ingestions treated conservatively without steroids, endoscopy, or nasogastric tube showed a stricture rate of 23%. Vomiting should not be induced and administration of buffering agents should be avoided to prevent an exothermic reaction in the stomach. Intravenous corticosteroids (eg, methylprednisolone, 1–2 mg/kg/day) are given immediately to reduce oral swelling and laryngeal edema. A recent study using high dose (1 g/1.73 m²) methylprednisolone for the first 3 days after ingestion, however, showed a significant decrease in the occurrence of esophageal strictures. Treatment may be stopped if there are only first-degree burns at endoscopy. Broad-spectrum antibiotic coverage with third-generation cephalosporins may be considered, to decrease stricture formation by preventing bacterial colonization into necrotic tissue. Acid-blockade is often used to decrease additional injury from acid reflux.

Esophageal strictures develop in areas of anatomic narrowing (thoracic inlet, GE junction, or point of compression where the left bronchus crosses the esophagus), where contact with the caustic agent is more prolonged. Strictures occur only with full-thickness esophageal necrosis and prevalence of stricture formation varies from 10% to 50%. Repeated esophageal dilations may be necessary as a stricture develops, with one review showing 35% requiring more than seven dilations. In that series of 175 patients, there was long-term success in only 16% of patients, with 4.5% having complications of perforation and a 2.8% mortality rate. In complicated cases esophageal stenting may be beneficial during early management. Newer, fully covered, self-expanding, removable esophageal stents, now available in pediatric sizes, may offer additional options for recurrent caustic strictures. Topical mitomycin-C has been effective in treatment of refractory caustic strictures of the esophagus, with one study showing a mean of 4.5 dilations per patient compared to 11 with intralumesl steroid injections. Animal models utilizing 5-fluorouracil in the early management of caustic esophageal injuries have also shown promise in preventing fibrosis and stricture formation. Surgical replacement of the esophagus by colonic interposition or gastric tube may be needed for long strictures resistant to dilation, though stricture rates may be as high as 47% and leaks as high as 18%. There has been a recent EoE case report of eosinophilic esophagitis that had developed following a caustic injury, leading to speculation of a causal effect.

Older infants and toddlers engage their environment, in part, by placing items in their mouth. As a result, accidental foreign body ingestions are a common occurrence in pediatrics. Fortunately, 80%–90% of foreign bodies pass spontaneously with only 10%–20% requiring endoscopic or surgical management. At presentation the most common symptoms of an ingested foreign body are dysphagia, odynophagia, drooling, regurgitation, and chest/abdominal pain. Dysphagia, odynophagia, drooling, regurgitation, and chest/abdominal pain are typical symptoms of esophageal foreign body. Esophageal foreign bodies should be removed within 24 hours of ingestion. Esophageal button batteries must be removed emergently because of their ability to cause lethal injury. Most foreign bodies in the stomach will pass spontaneously.

References
lodge in narrowed areas—valleculae, thoracic inlet, GE junction, pylorus, ligament of Treitz, and ileocecal junction, or at the site of congenital or acquired intestinal stenoses. The evaluation of a swallowed foreign body starts with plain radiography. Radio-opaque objects will be easily visualized. Non–radio-opaque objects, such as plastic toys, may not appear on standard radiograph. If there is particular concern, based on patient symptoms, for a retained esophageal foreign body that is non–radio-opaque, a contrast esophagram is a useful test. Use of contrast, however, may delay or increase the risk of anesthesia due to aspiration concerns.

Most foreign bodies can be removed from the esophagus or stomach of a child by a skilled endoscopist. During removal of an esophageal foreign body, there is increased risk of aspiration and the airway should be protected via intubation with an endotracheal tube. Esophageal foreign bodies should be removed within 24 hours to avoid injury to the esophagus. The urgency of removal of esophageal foreign bodies is dictated by the severity of patient symptoms and the ability to pass oral secretions into the stomach.

Disk-shaped button batteries lodged in the esophagus are especially concerning and should be removed immediately. Button batteries may cause an electrical thermal injury in as little as 2 hours and have resulted in death from subsequent aortoenteric fistula formation, even weeks after battery removal. Although most button batteries in the stomach will pass uneventfully, greater attention is required for larger batteries (> 20 mm) in younger children (< 5 years of age), as there is greater risk for injury sustained to the esophagus and the battery is less likely to successfully traverse the pylorus. In these cases, endoscopic evaluation with gastric batteries may still be considered in order to evaluate the esophagus for signs of injury and to remove the gastric battery. Rates of significant injury and death due to swallowed button batteries have increased in recent years with the transition toward production of higher-voltage lithium batteries.

Esophageal food impaction should always raise the question of underlying esophagitis. In particular, EoE has been shown to be present in up to 75% of pediatric patients presenting initially with esophageal food impaction.

Smooth foreign bodies in the stomach, such as buttons or coins, may be monitored without attempting removal for up to several weeks if the child is free of symptoms. Screws and nails are examples of objects with a blunt end that is heavier than the sharp end. These asymmetrically weighted objects will generally pass without incident and so need for endoscopic removal must be considered on a case-by-case basis. In contrast, double-sided sharp objects that are weighted equally on each end, such as fishbones and wooden toothpicks, should be removed as they can migrate through the wall of the GI tract into the pericardium, liver, and inferior vena cava. Large, open safety pins should be removed from the stomach because they may not pass the pyloric sphincter and may cause perforation. Objects longer than 5 cm may be unable to pass the ligament of Treitz and should be removed. Magnets require consideration for removal only if there has been more than one ingested, or if a single magnet was ingested along with a metallic object, because of the risk of fistula or erosion of mucosal tissue trapped between two adherent foreign bodies. Rare earth metal magnets, or neodymium magnets, are very powerful small magnets that are sold in bulk and have caused multiple cases of bowel perforation necessitating surgical intervention. Ingestion of multiple magnets should lead to immediate endoscopic removal if technically feasible. If not, their migration through the GI tract should be followed radiographically until they are passed.

The use of balanced electrolyte lavage solutions containing polyethylene glycol may help the passage of small, smooth foreign bodies lodged in the intestine. Lavage is especially useful in hastening the passage of foreign bodies that may contain an absorbable toxic material such as a heavy metal.

HIATAL HERNIA
In paraesophageal hiatal hernias (HH), the esophagus and GE junction are in their normal anatomic position, but the gastric cardia is herniated through the diaphragmatic hiatus. In sliding HH, the GE junction and a portion of the proximal stomach are displaced above the diaphragmatic hiatus. Sliding HH are common, with a recent study showing a prevalence of nearly 21% of all EGD’s performed and a correlation between HH and clinical symptoms of heartburn and regurgitation in children > 48 months. Conversely, congenital paraesophageal hernias are rare in childhood; patients may present with recurrent pulmonary infections, vomiting, anemia, failure to thrive, or dysphagia. The median age at diagnosis was 35 days and 36% had concomitant congenital anomalies in one retrospective series. The most common cause of acquired paraesophageal hernia is previous fundoplication surgery. Radiographic studies typically reveal a cystic mass in the posterior mediastinum or a dilated esophagus. The diagnosis is typically made with an upper GI series or a CT scan of the chest and abdomen, though diagnosis via ultrasound in the prenatal period has been reported. Presence of a Schatzki ring on upper GI has been found to be associated with HH in 96% of children and should increase the index of suspicion. Additionally, the absence of a periesophageal fat pad on CT or ultrasound of the chest has been found to be a marker of HH. Recently, use of pH Impedance probe testing has been proposed as an effective method to identify HH in children, where inversion of the usual acid:nonacid reflux ratio to > 1.0 had a sensitivity of 93.8% and specificity of 79.6%. Treatment in symptomatic cases is generally surgical, with laparoscopic repair being used more commonly. The laparoscopic approach has been shown to have longer surgical times but a shorter time to advancement to full enteral feeding compared to the open surgical approach, with no change in complications. Controversy exists about using biosynthetic mesh for repair, as it decreases the risk of recurrent hernia but also increases esophageal erosion in children. Fundoplication is indicated if paraesophageal or sliding HH produces persistent symptoms, though the presence of a preoperative HH has been found to triple the risk of recurrent GERD following fundoplication. Comparison of Nissen versus Thal fundoplication in pediatric HH patients showed no significant difference in outcomes.

PYLORIC STENOSIS
ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES
- Postnatal muscular hypertrophy of the pylorus.
- Progressive gastric outlet obstruction, nonbilious vomiting, dehydration, and alkalosis in infants younger than 12 weeks.
- Upper GI contrast radiographs or abdominal ultrasound are diagnostic.

The cause of postnatal pyloric muscular hypertrophy with gastric outlet obstruction is unknown. The incidence is 1–8 per 1000 births, with a 4:1 male predominance. Recent studies suggest that erythromycin in the neonatal period is associated with a higher incidence of pyloric stenosis.

Clinical Findings
A. Symptoms and Signs
Projectile postprandial vomiting usually begins between 2 and 4 weeks of age but may start as late as 12 weeks. Vomiting starts at birth in about 10% of cases and onset of symptoms may be delayed in preterm infants. Vomitus is rarely bilious but may be blood-streaked. Infants are usually hungry and nurse avidly. The upper abdomen may be distended after feeding, and prominent gastric peristaltic waves from left to right may be seen. An oval mass, 5–15 mm in longest dimension can be felt on deep palpation in the right upper abdomen, especially after vomiting. This palpable “olive,” however, was only present in 13.6% of patients studied.

B. Laboratory Findings
Hypochloremic alkalosis with potassium depletion is the classic metabolic findings, though low chloride may be seen in as few as 23% and alkalosis in 14.4%. These findings may not be as common in younger infants and their absence should not dissuade from the diagnosis in the appropriate clinical setting. Dehydration causes elevated hemoglobin and hematocrit. Mild unconjugated bilirubinemia occurs in 2%–5% of cases.
C. Imaging

Ultrasonography shows a hypoechoic muscle ring greater than 4 mm thickness with a hyperdense center and a pyloric channel length greater than 15 mm. A barium upper GI series reveals retention of contrast in the stomach and a long narrow pyloric channel with a double track of barium. The hypertrophied muscle mass produces typical semilunar filling defects in the antrum. Infants presenting younger than 21 days may not fulfill these classic ultrasonographic criteria and may require clinical judgment to interpret "borderline" measures of pyloric muscle thickness.

» Treatment & Prognosis

Ramstedt pyloromyotomy is the treatment of choice and consists of incision down to the mucosa along the pyloric length. The procedure can be performed laparoscopically, with similar efficacy. Treatment of dehydration and electrolyte imbalance is mandatory before surgical treatment, even if it takes 24–48 hours. Patients often vomit postoperatively as a consequence of gastritis, esophagitis, or associated GE reflux. The outlook after surgery is excellent, though patients may show as much as a four times greater risk for development of chronic abdominal pain of childhood. Postoperative barium radiograph remains abnormal for many months despite relief of symptoms.

GASTRIC & DUODENAL ULCER

» Localized erosions of gastric or duodenal mucosa.
» Pain, vomiting, and bleeding are the most common symptoms.
» Underlying severe illness, Helicobacter pylori infection, and nonsteroidal anti-inflammatory drugs (NSAIDs) are the most common causes.

» Successful eradication of H pylori infection requires knowledge of regional antimicrobial resistance patterns.
» Diagnosis by endoscopy.

» General Considerations

Gastric and duodenal ulcers occur at any age. In the United States, most childhood gastric and duodenal ulcers are associated with underlying illness, toxins, or drugs such as NSAIDS that cause breakdown in mucosal defenses.

Worldwide, the most common cause of gastric and duodenal ulcer is mucosal infection with the bacterium H pylori. The prevalence of H pylori infection varies greatly by country of origin and increases with poor sanitation, crowded living conditions, and family exposure. Infection is thought to be acquired in childhood, but only in a small percentage of infected persons will infection lead to nodular gastritis, peptic ulcer, or in the case of long-standing infection, gastric lymphoid tumors, and adenocarcinoma of the stomach. Some bacterial virulence factors have been identified, but the host and bacterial characteristics that contribute to disease progression are still largely unknown. In contrast to ulcers secondary to H pylori, non–H pylori ulcers tend to present at a younger age and are more likely to recur. In a large study of over 1000 children undergoing endoscopy, 5.4% had ulcers, with 47% of these due to H pylori, 16.5% related to NSAIDs, and 35.8% unrelated to either H pylori or NSAIDs. Recent evidence suggests that the prevalence of non–H pylori peptic ulcers is increasing.

Illnesses predisposing to secondary ulcers include central nervous system (CNS) disease, burns, sepsis, multiorgan system failure, chronic lung disease, Crohn disease (CrD), cirrhosis, and rheumatoid arthritis. The most common drugs causing secondary ulcers are aspirin, alcohol, and NSAIDs. NSAID use may lead to ulcers throughout the GI tract but most often in the stomach and duodenum. Severe ulcerative lesions in full-term neonates have been found to be associated with maternal antacid use in the last month of pregnancy.

» Clinical Findings

A. Symptoms and Signs

In children younger than 6 years, vomiting and upper GI bleeding are the most common symptoms of gastric and duodenal ulcer. Older children are more likely to complain of epigastric abdominal pain. Ulcers in the pyloric channel may cause gastric outlet obstruction. Chronic blood loss may cause iron deficiency anemia. Deep penetration of the ulcer may erode into a mucosal arteriole and cause acute hemorrhage. Penetrating duodenal ulcers (especially common during cancer chemotherapy, immunosuppression, and in
the intensive care setting) may perforate the duodenal wall, resulting in peritonitis or abscess.

B. Diagnostic Studies

Upper GI endoscopy is the most accurate diagnostic examination. The typical endoscopic appearance of an ulcer is a white exudative base with erythematous margins (Figure 21–4). Histopathologic assessment of biopsies obtained at endoscopy provides the opportunity to distinguish between different causes of ulcer disease, including *H pylori* infection, eosinophilic GI disease, celiac disease (CD), and CrD. Endoscopic diagnosis of active *H pylori* infection may be achieved by histologic examination of gastric biopsies or measurement of urease activity on gastric tissue specimens. Additional noninvasive methods of diagnosis of active *H pylori* infection include evaluation of breath for radiolabeled carbon dioxide after administration of radiolabeled urea by mouth and detection of *H pylori* antigen in the stool. False-negative results for the latter two tests have been described when the patient is taking a PPI. Serum antibodies against *H pylori* have poor sensitivity and specificity, and do not prove that there is active infection or that treatment is needed. For severe or recurrent ulcerations not caused by *H pylori*, stress, or medications, a serum gastrin level may be considered to evaluate for a gastrin-secreting tumor (Zollinger-Ellison syndrome), though mild to moderate elevation in gastrin levels can be seen with use of PPI drugs. Upper GI barium radiographs may show an ulcer crater. Radiologic signs suggestive of peptic disease in adults (duodenal spasticity and thick irregular folds) are not reliable indicators in children.

Treatment

Treatment of symptomatic *H pylori* infection requires eradication of the organism, a goal that remains elusive in children. The optimal medical regimen is still undetermined. Standard first-line triple therapy for eradication of *H pylori* has traditionally been a 7–10 day treatment course involving simultaneous use of two oral antibiotics (most commonly, amoxicillin and clarithromycin) and PPI. However, rising rates of resistance to clarithromycin have rendered this combination ineffective in certain parts of the world. As a result, many alternative combinations of antimicrobials (such as bismuth, metronidazole, imidazole, tetracycline, and levofloxacin) have been evaluated. Because resistance to antibiotics varies greatly by country, regional antibiotic resistance patterns for *H pylori* should be a guide in selecting initial therapy. Sequential therapy, which involves induction with a single antibiotic plus PPI for 5 days followed by addition of a second antibiotic for an additional 5 days, has not conclusively been shown to improve treatment performance in children. Test of cure can be achieved by either the urease breath test or fecal *H pylori* antigen test.

CONGENITAL DIAPHRAGMATIC HERNIA

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Congenital diaphragmatic hernia (CDH) typically is diagnosed prenatally by screening ultrasound.
- Pulmonary hypoplasia and cardiovascular dysfunction are clinical challenges in the postnatal period.
- After surgical repair, chronic pulmonary disease and GER can be lifelong morbidities.

Herniation of abdominal contents through the diaphragm usually occurs through a posterolateral defect involving the left side of the diaphragm (foramen of Bochdalek).
In about 9% of cases, the diaphragmatic defect is retrosternal (foramen of Morgagni). In eversion of the diaphragm, a subtype of CDH, a leaf of the diaphragm with hypoplastic muscular elements balloons into the chest and is asymptomatic or leads to milder symptoms. Hernias result from failure of the embryologic diaphragmatic anlagen to fuse and divide the thoracic and abdominal cavities at 8–10 weeks’ gestation. The herniation of abdominal contents into the thoracic cavity can lead to pulmonary hypoplasia and significant cardiovascular dysfunction after birth, in particular severe persistent pulmonary hypertension.

Diagnosis of CDH is typically made prenatally by ultrasound. Associated congenital malformations, most commonly cardiovascular, may be detected prenatally. With the advent of improved care of cardiopulmonary disease in the newborn period, including the use of inhaled nitric oxide, high-frequency oscillatory ventilation, and extracorporeal membrane oxygenation, survival has improved for infants with CDH and is as high as 70%–90% in some centers. Antenatal intervention with fetal tracheal occlusion may improve survival in CDH associated with severe pulmonary hypoplasia. Operative repair of the diaphragmatic defect is usually performed in the newborn period once cardiopulmonary stabilization is achieved, with increasing utilization of laparoscopic and thoracoscopic minimally invasive approaches. Occasionally, diaphragmatic hernia is first identified in an older infant or child during incidental radiograph or routine physical examination. These children usually have a much more favorable prognosis than neonates. Long-term health issues in CDH survivors include chronic pulmonary disease, pulmonary hypertension, neurodevelopmental delays, hearing loss, and gastroesophageal reflux.

**CONGENITAL DUODENAL OBSTRUCTION**

» General Considerations

Obstruction is generally classified into intrinsic and extrinsic causes, although rare cases of simultaneous intrinsic and extrinsic anomalies have been reported.

Etiologies of extrinsic duodenal obstruction include congenital peritoneal bands associated with intestinal malrotation, annular pancreas, or duodenal duplication. Intrinsic duodenal obstruction is more common and is typically associated with congenital atresia, stenosis, or mucosal webs (so-called “wind sock deformity”). In about two-thirds of patients with congenital duodenal obstruction, there are other associated anomalies.

**Imaging Studies**

Diagnosis of congenital duodenal obstructions is often made prenatally by ultrasound. Prenatal diagnosis predicts complete obstruction in 77% of cases and is associated with polyhydramnios, prematurity, and higher risk of maternal-fetal complications. Presence of a “double bubble” on ultrasound and an echogenic band in the second portion of the duodenum are 100% sensitive and specific for an annular pancreas. Postnatal abdominal plain radiographs show gaseous distention of the stomach and proximal duodenum (the “double-bubble” radiologic sign). With protracted vomiting, there is less air in the stomach and less abdominal distention. Absence of distal intestinal gas suggests atresia or severe extrinsic obstruction, whereas a pattern of intestinal air scattered over the lower abdomen may indicate partial duodenal obstruction. Barium enema may be helpful in determining the presence of malrotation or atresia in the lower GI tract, as well as evaluating for radiographic evidence of Hirschsprung disease, which may also present with abdominal distension and vomiting.

**Clinical Findings**

A. Duodenal Atresia

Maternal polyhydramnios is common and often leads to prenatal diagnosis by ultrasonography. Vomiting (usually bile-stained) and epigastric distention begin within a few hours of birth. Meconium may be passed normally. Duodenal atresia is often associated with other congenital anomalies (30%), including esophageal atresia, intestinal atresias, and cardiac and renal anomalies. Prematurity (25%–50%) and Down syndrome (20%–30%) are also associated with duodenal atresia.

B. Duodenal Stenosis

In this condition, duodenal obstruction is not complete. Onset of obvious obstructive symptoms may be delayed for weeks or years. Although the stenotic area is usually distal to the ampulla of Vater, the vomiting does not always contain bile. Duodenal stenosis or atresia is the most common GI tract malformation in children with Down syndrome, occurring in 3.9%.

C. Annular Pancreas

Annular pancreas is a rotational defect in which normal fusion of the dorsal and ventral pancreatic anlagen does not occur, and a ring of pancreatic tissue encircles the duodenum. The presenting symptom is duodenal obstruction. Down syndrome and congenital anomalies of the GI tract occur frequently. Polyhydramnios is common. Symptoms may develop late in childhood or even in adulthood if the obstruction is not complete in infancy. Treatment consists of duodenoduodenostomy or duodenojunostomy without operative dissection or division of the pancreatic anulus. Pancreatic function is normal.
# Treatment & Prognosis

In almost all settings, surgical intervention (either laparoscopic or open) is required for congenital duodenal obstructive lesions. Typically, duodenoduodenostomy is performed to bypass the area of stenosis or atresia. For duodenal stenoses, however, there have been isolated reports of successful endoscopic treatment with balloon dilation. Thorough surgical exploration is typically done to ensure that no lower GI tract anomalies are present. More recent reports document the safety and utility of a laparoscopic approach. The mortality rate is increased in infants with prematurity, Down syndrome, and associated congenital anomalies. Duodenal dilation and hypomotility from antenatal obstruction may cause duodenal dysmotility with obstructive symptoms even after surgical treatment. Placement of transanastomotic feeding tubes at the time of the initial repair has been found to result in more rapid progression to full enteral feeds and decreased need for parenteral nutrition (PN). The overall prognosis for these patients is good, with the majority of their mortality risk due to associated anomalies other than duodenal obstruction.

## DISORDERS OF THE SMALL INTESTINE

### INTESTINAL ATRESIA & STENOSIS

Excluding anal anomalies, intestinal atresia or stenosis accounts for one-third of all cases of neonatal intestinal obstruction (see Chapter 1). Antenatal ultrasound can identify intestinal atresia in utero; polyhydramnios occurs in most affected pregnancies. Sensitivity of antenatal ultrasound is greater in more proximal atresias. Other congenital anomalies may be present in up to 54% of cases and 52% are delivered preterm. In apparently isolated atresia cases, occult congenital cardiac anomalies have been reported in as many as 30%. In one large population-based study, the prevalence was 2.9 per 10,000 births, although there is some evidence that the prevalence may be increasing. The localization and relative incidence of atresias and stenoses are listed in Table 21–1. Although jejunal and ileal atresias are often grouped together, there are data to suggest that jejunal atresias are associated with increased morbidity and mortality compared to ileal atresia. These differences may be related to increased compliance of the jejunal wall, resulting in more proximal dilation and subsequent loss in peristaltic activity.

Bile-stained vomiting and abdominal distention begin in the first 48 hours of life. Multiple sites in the intestine may be affected and the overall length of the small intestine may be significantly shortened. Radiographic features include dilated loops of small bowel and absence of colonic gas. Barium enema reveals narrow-caliber microcolon because of lack of intestinal flow distal to the atresia. In over 10% of patients with intestinal atresia, the mesentery is absent and the SMA cannot be identified beyond the origin of the right colic and ileocolic arteries. The ileum coils around one of these two arteries, giving rise to the so-called Christmas tree deformity on contrast radiographs. The tenuous blood supply often compromises surgical anastomoses. The differential diagnosis of intestinal atresia includes Hirschsprung disease, paralytic ileus secondary to sepsis, midgut volvulus, and meconium ileus. Surgery is mandatory. Postoperative complications include short bowel syndrome (SBS) in 15% and small bowel hypomotility secondary to antenatal obstruction. Overall mortality has been reported at 8%, with increased risk in low-birthweight and premature infants.

INTESTINAL MALROTATION

General Considerations

The midgut extends from the duodenojejunal junction to the mid-transverse colon. It is supplied by the superior mesenteric artery (SMA), which runs in the root of the mesentery. During gestation, the midgut elongates into the umbilical sac, returning to an intra-abdominal position during the 10th week of gestation. The root of the mesentery rotates in a counterclockwise direction during retraction causing the colon to cross the abdominal cavity ventrally. The cecum moves from the left to the right lower quadrant, and the duodenum crosses dorsally becoming partly retroperitoneal. When rotation is incomplete, the dorsal fixation of the mesentery is defective and shortened, so that the bowel from the ligament of Treitz to the mid-transverse colon may rotate around its narrow mesenteric root and occlude the SMA (volvulus). From autopsy studies it is estimated that up to 1% of the general population may have intestinal malrotation, which is diagnosed in the first year of life in 70%–90% of patients.

Clinical Findings

A. Symptoms and Signs

Malrotation with volvulus accounts for 10% of neonatal intestinal obstructions. Most infants present in the first 3 weeks of life with bile-stained vomiting or with overt small bowel obstruction. Intrauterine volvulus may cause intestinal obstruction or perforation at birth. The neonate may present with ascites or meconium peritonitis. Later presenting signs include intermittent intestinal obstruction, malabsorption, protein-losing enteropathy, or diarrhea. Associated congenital anomalies, especially cardiac, occur in over 25% of symptomatic patients. Many of these may be found in a subgroup of malrotation patients with heterotaxy syndromes, with associated asplenia or polysplenia. Older children and adults with undiagnosed malrotation typically present with chronic GI symptoms of nausea, vomiting, diarrhea, abdominal pain, dyspepsia, bloating, and early satiety.

B. Imaging

An upper GI series is considered the gold standard for diagnosis, with a reported sensitivity of 96%, and classically shows the duodenojejunal junction and the jejunum on the right side of the spine. The diagnosis of malrotation can be further confirmed by barium enema, which may demonstrate a mobile cecum located in the midline, right upper quadrant, or left abdomen. Plain films of the abdomen in the newborn period may show a “double-bubble” sign, resulting in a misdiagnosis of duodenal atresia. CT scan and ultrasound of the abdomen may be used to make the diagnosis as well and are characterized by the “whirlpool sign” denoting midgut volvulus. Reversal of the normal position of the SMA and superior mesenteric vein (SMV) may be seen in malrotation, though normal position may be found in up to 29% of patients. Identification of the third portion of the duodenum within the retroperitoneum makes malrotation very unlikely.

Treatment & Prognosis

Surgical treatment of malrotation is the Ladd procedure. In young infants the Ladd procedure should be performed even if volvulus has not occurred. The duodenum is mobilized, the short mesenteric root is extended, and the bowel is then fixed in a more normal distribution. Treatment of malrotation discovered in children older than 12 months is uncertain. Because volvulus can occur at any age, surgical repair is usually recommended, even in asymptomatic children. Laparoscopic repair of malrotation is possible but is technically difficult and is never performed in the presence of volvulus.

Midgut volvulus is a surgical emergency. Bowel necrosis results from occlusion of the SMA. When necrosis is extensive, it is recommended that a first operation include only reduction of the volvulus with lysis of mesenteric bands. Resection of necrotic bowel should be delayed if possible until a second-look operation 24–48 hours later can be undertaken in the hope that more bowel can be salvaged. The prognosis is guarded if perforation, peritonitis, or extensive intestinal necrosis is present. Mid-gut volvulus is one of the most common indications for small bowel transplant in children, responsible for 10% of cases in a recent series.

Short Bowel Syndrome

General Considerations

Short bowel syndrome (SBS) is defined as a condition resulting from reduced intestinal absorptive surface that leads to alteration in intestinal function that compromises normal growth, fluid/electrolyte balance, or hydration status. The vast majority of pediatric patients with SBS have undergone neonatal surgical resection of intestine. The most common etiologies in children are necrotizing enterocolitis (45%); intestinal atresias (23%); gastroschisis...
requiring continuous delivery of an elemental formula surgery, and has been shown to improve outcomes. Enteral patient care, involving gastroenterology, nutrition, and refers to the multidisciplinary team approach to individual intestinal rehabilitation for the child with SBS and IF, treatments of the underlying intestinal disorder or PN therapy. Other complication–related bloodstream infections are relatively common in pediatric patients on PN and may progress to end-stage liver disease in 10% of affected patients. Recurrent catheter–related bloodstream infections include strategies to manage or prevent complications related to PN therapy, including infection and liver disease. Antimicrobial lock solutions distilled into central venous catheters using either ethanol or antibiotics may have a role in reducing infection rates. Compelling evidence over the past several years suggests that modification of parenteral lipid solution, either through reduction in dose of soy-based intralipid or replacement with a third-generation lipid solution (Omega- 3 or SMOF lipid), improves outcomes associated with PNALD in pediatric patients.

Autologous bowel reconstructive surgery (bowel lengthening) should be considered in a patient who is failing to advance enterally and has anatomy amendable to surgical intervention, typically with regards to adequate bowel dilation. Both the serial transverse enteroplasty (STEP) procedure and longitudinal intestinal lengthening and tailoring (Bianchi) procedure have been successful in allowing weaning from TPN in up to 50% of patients in reported series. In recent years, the STEP procedure has gained favor as being potentially less technically demanding and repeatable, if the bowel dilates sufficiently after the initial procedure.

When medical, nutritional, and surgical managements fail, intestinal transplantation may be considered for a child with refractory and life-threatening complications of IF. Current outcome data after pediatric intestinal transplantation suggest 1- and 3-year survival rates of 83% and 60%, respectively.

INTUSSUSCEPTION

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Intussusception is the most common cause of bowel obstruction in the first 2 years of life.
- The most common location for intussusception is ileocolic and 85% of cases are idiopathic.
- Ultrasound is the most sensitive and specific diagnostic modality for intussusception.
- Air enema is the best therapeutic approach in the stable patient, with successful reduction in 75% of cases.

Intussusception is the invagination of one segment of intestine into another segment. Although intussusception can occur anywhere along the small and large bowel, most commonly the intussusception starts just proximal to the ileocecal valve and extends for varying distances into the colon. Swelling, hemorrhage, incarceration, vascular compromise, and necrosis of the intussuscepted ileum may occur, potentially resulting in intestinal perforation and peritonitis. Intussusception is the most frequent cause of intestinal obstruction in the first 2 years of life. It is three times more common in males than in females. In 85% of cases the cause is idiopathic but the likelihood of identifying a cause of intussusception increases with the age of the patient. Implicated primary causes of intussusception include small bowel polyp, Meckel diverticulum, omphalomesenteric remnant, duplication, lymphoma, lipoma, parasites, foreign bodies, and viral enteritis with hypertrophy of Peyer patches. Intussusception of the small bowel can also be seen in CD, cystic fibrosis, and Henoch-Schönlein purpura. In children older than 6 years, lymphoma is the most common cause of intussusception.

**Clinical Findings**

Classically, a previously healthy infant 3–12 months of age develops recurring paroxysms of abdominal pain with screaming and drawing up of the knees. Vomiting and diarrhea occur soon afterward (90% of cases), and bloody bowel movements with mucus appear within the next 12 hours (50%). The child is characteristically lethargic between paroxysms and may be febrile. The abdomen is tender and often distended. A sausage-shaped mass may be palpated, usually in the upper mid abdomen. The likelihood of bowel compromise increases with the duration of symptoms. In older children, sudden attacks of abdominal pain may be related to chronic recurrent intussusception with spontaneous reduction.

**Diagnosis & Treatment**

The constellation of abdominal pain, lethargy, vomiting, and a suspicious abdominal radiograph was found to have a sensitivity of 95% in identifying intussusceptions in children. Abdominal radiographs alone, however, are poorly sensitive for the diagnosis of intussusception. Abdominal ultrasound carries sensitivity for diagnosis of intussusception of 98%–100%. Barium enema and air enema are both diagnostic and therapeutic. Reduction of the intussusception by barium enema should not be attempted if signs of strangulated bowel, perforation, or toxicity are present. Air insufflation of the colon under fluoroscopic guidance is a safe alternative to barium enema that has excellent diagnostic sensitivity and specificity without the risk of contaminating the abdominal cavity with barium. Rates of successful reduction by air enema approach 75%. When initial enema reduction is successful, recurrence of intussusception within 24–48 hours occurs in less than 5% of patients. The rate of perforation with either liquid or air enema is approximately 1%. Care is required in patient selection for either air or barium enema because if ischemic damage to the intestine is suspected based on symptom severity (shock or sepsis), the risk of perforation increases and surgical reduction is preferred. Surgery is thus required for extremely ill patients, in patients with evidence of bowel perforation, or in those in whom hydrostatic or pneumatic reduction has been unsuccessful (25%). Surgery has the advantage of identifying a lead point such as Meckel diverticulum, lymphoma, or small bowel polyp. Surgical reduction of intussusception is associated with a lower recurrence rate than pneumatic reduction.

**Prognosis**

The likelihood of successful reduction by enema decreases if symptom duration is greater than 24 hours. Of those requiring surgical reduction, the risk of subsequent bowel resection increased from 17% to 39% in patients with symptoms greater than 24 hours. Overall mortality rate with treatment is 1%–2%.

**INGUINAL HERNIA**

Inguinal hernias are most often indirect and occur more frequently (9:1) in boys than in girls. Hernias may present at any age. The incidence in preterm male infants is close to 5% and is reported in 30% of male infants weighing 1000 g or less.

**Clinical Findings**

In most cases, a hernia is a painless inguinal swelling. Parents may be the only one to see the mass, as it may
GASTROINTESTINAL TRACT

retract when the infant is active, cold, frightened, or agitated. A history of inguinal fullness associated with coughing or long periods of standing, or presence of a firm, globular, and tender swelling, sometimes associated with vomiting and abdominal distention are clinical clues. In some instances, a herniated loop of intestine may become partially obstructed leading to severe pain. Rarely, bowel becomes trapped in the hernia sac, and complete intestinal obstruction occurs. Gangrene of the hernia contents or testis may occur. In girls, the ovary may prolapse into the hernia sac presenting as a mass below the inguinal ligament. A suggestive history often is the only criterion for diagnosis, along with the “silk glove” feel of the rubbing together of the two walls of the empty hernia sac.

Differential Diagnosis

Inguinal lymph nodes may be mistaken for a hernia. Nodes are usually multiple with more discrete borders. A hydrocele of the cord should transilluminate. An undescended testis is usually mobile in the canal and is associated with absence of the gonad in the scrotum.

Treatment

Incarceration of an inguinal hernia is more likely to occur in boys and in children younger than 10 months. Manual reduction of incarcerated inguinal hernias can be attempted after the sedated infant is placed in the Trendelenburg position with an ice bag on the affected side. Manual reduction is contraindicated if incarceration has been present for more than 12 hours or if bloody stools are noted. Surgery is indicated if a hernia has ever incarcerated. Hydroceles frequently resolve by age 2 years.

The omphalomesenteric duct connects the fetal yolk sac to the developing gut. This duct is usually obliterated early in embryologic development, but failure of this process can lead to a variety of structures that originate from the embryonic duct remnant connecting the ileum to the undersurface of the umbilicus. If the remnant is patent, it can lead to herniation of intestinal contents into the umbilical cord or lead to fecal discharge from the umbilicus. A fibrous cord may become the focal point for volvulus and resulting intestinal obstruction. Mucoid umbilical discharge may indicate a mucocele in the omphalomesenteric remnant with an opening at the umbilicus. A closed mucocele may protrude through the umbilicus and appear as a polypoid mass that may be mistaken for an umbilical granuloma because it is firm and bright red.

Cauterization of a mucocele is not recommended. Surgical excision of omphalomesenteric remnants is indicated. Ultrasound examination or abdominal computed tomography (CT) can help confirm the diagnosis of an omphalomesenteric duct remnant.

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Persistent umbilical discharge in an infant may represent a patent omphalomesenteric duct.
- Ultrasound is the preferred diagnostic method for patent omphalomesenteric duct.
- Surgical excision of the omphalomesenteric remnant is required.

MECKEL DIVERTICULUM

Meckel diverticulum is the most common form of omphalomesenteric duct remnant and is usually located on the antimesenteric border of the mid to distal ileum. It occurs in 1.5% of the population and in the majority of cases causes no symptoms. Familial cases have been reported. If complications occur, they are three times more common in males than in females. More than 50% of complications occur in the first 2 years of life.
Clinical Findings
A. Symptoms and Signs
Forty to 60% of symptomatic patients have painless episodes of maroon or melanotic rectal bleeding. Bleeding is due to deep ileal ulcers adjacent to the diverticulum caused by acid secreted by heterotopic gastric tissue and may be voluminous enough to cause shock and anemia. Occult bleeding is less common. Intestinal obstruction occurs in 25% of symptomatic patients as a result of ileocolonic intussusception. Intestinal volvulus may occur around a fibrous remnant of the vitelline duct extending from the tip of the diverticulum to the abdominal wall. Meckel diverticula may be trapped in an inguinal hernia. Diverticulitis is clinically indistinguishable from acute appendicitis.

B. Imaging
Diagnosis of Meckel diverticulum is made with a Meckel scan. Technetium-99m (99mTc)-pertechnetate is taken up by the heterotopic gastric mucosa in the diverticulum and outlines the diverticulum on a nuclear scan. Giving pentagastrin or cimetidine before administering the radionuclide increases 99mTc-pertechnetate uptake and retention by the heterotopic gastric mucosa, and can increase the sensitivity of the test.

Treatment & Prognosis
Treatment is surgical and the prognosis for Meckel diverticulum is good.

ACUTE APPENDICITIS

General Considerations
Acute appendicitis is the most common indication for emergency abdominal surgery in childhood. The frequency increases with age and peaks between 15 and 30 years. Obstruction of the appendix by fecalith (25%) is a common predisposing factor. Parasites may rarely cause obstruction (especially ascariids). Most of the remaining cases are idiopathic.

The incidence of perforation is high in childhood (40%), especially in children younger than 2 years, in whom pain is often poorly localized and symptoms nonspecific. To avoid delay in diagnosis, it is important to maintain close communication with parents and perform a thorough initial physical examination with sequential examinations at frequent intervals over several hours to correctly interpret the evolving symptoms and signs.

Clinical Findings
A. Symptoms and Signs
The typical patient has fever and periumbilical abdominal pain, which then localizes to the right lower quadrant with signs of peritoneal irritation. Anorexia, vomiting, constipation, and diarrhea also occur. Contrary to the vomiting of acute gastroenteritis, which usually precedes abdominal pain, vomiting in appendicitis usually follows the onset of pain and is often bilious. The clinical picture is frequently atypical, especially in young children and infants. A rectal examination may clarify the site of tenderness or reveal a localized appendiceal mass. Serial examinations are critical in differentiating appendicitis from the many other conditions that transiently mimic its symptoms.

B. Laboratory Findings
The white blood cell count is seldom higher than 15,000/μL. Pyuria, fecal leukocytes, and guaiac-positive stool are sometimes present. The combination of elevated C-reactive protein (CRP) and leukocytosis has been reported to have positive predictive value of 92% for acute appendicitis, although having normal values for both measures does not exclude the diagnosis. Levels of interleukin 6 (IL-6) show promise as a potential biomarker for acute appendicitis, usually peaking within 24 hours of onset of pain.

C. Imaging
A radio-opaque fecalith reportedly is present in two-thirds of cases of ruptured appendix. In experienced hands, ultrasonography of the appendix shows a noncompressible, thickened appendix in 93% of cases. Abdominal CT after rectal instillation of contrast with thin cuts in the area of the appendix may be diagnostic. An otherwise normal abdominal CT scan with a nonvisualized appendix has still been reported to have a negative predictive value of 99%. Analysis of diagnostic strategies for pediatric patients with suspected appendicitis has shown abdominal ultrasound, followed by CT scan for negative studies, to be the most cost-effective diagnostic approach compared to CT or ultrasound alone.

Differential Diagnosis
The presence of pneumonia, pleural effusion, urinary tract infection, right-sided kidney stone, cholecystitis, perihepatitis, and pelvic inflammatory disease may mimic appendicitis. Acute gastroenteritis with *Yersinia enterocolitica* may present as pseudoappendicitis in 17% of cases. Other medical and surgical conditions causing acute abdomen should also be considered (see Table 21–7).

Treatment & Prognosis
Exploratory laparotomy or laparoscopy is indicated when the diagnosis of acute appendicitis cannot be ruled out after a period of close observation. Postoperative antibiotic therapy is reserved for patients with gangrenous or perforated appendix. The mortality rate is less than 1% during childhood, despite the high incidence of perforation.
In uncomplicated nonruptured appendicitis, a laparoscopic approach is associated with a shortened hospital stay.

**DUPLICATIONS OF THE GASTROINTESTINAL TRACT**

Enteric duplications are congenital spherical or tubular structures found most commonly in the ileum but can also be found in the duodenum, rectum, and esophagus. Most duplications do not communicate with the intestinal lumen. Some duplications (neuroenteric cysts) are attached to the spinal cord and are associated with hemivertebrae and anterior or posterior spina bifida.

Symptoms of vomiting, abdominal distention, colicky pain, rectal bleeding, partial or total intestinal obstruction, or an abdominal mass may start in infancy. Diarrhea and malabsorption may result from bacterial overgrowth in communicating duplications. Physical examination may reveal a rounded, smooth, movable mass, and a distended abdomen with prominent veins and visible peristaltic waves with palpable fecal masses. Intermittent bouts of intestinal obstruction, hypotension, and proteinemia, and failure to thrive are common. Encopresis is rare.

Failure of the newborn to pass meconium, followed by vomiting, abdominal distention, and reluctance to feed, suggests the diagnosis of Hirschsprung disease. Most children with Hirschsprung disease do not pass stool in the first 24 hours of their life. Enteroctolitis manifest by fever, explosive diarrhea, and prostration is reported in approximately 50% of affected newborns. Enteroctolitis may lead to inflammatory and ischemic changes in the colon, with perforation and sepsis. In some patients, especially those with short segments involved, symptoms are not obvious at birth. In later infancy, alternating obstipation and diarrhea predominate. The older child is more likely to have constipation alone. Symptoms can include foul-smelling or ribbon-like stools, a distended abdomen with prominent veins and visible peristaltic waves with palpable fecal masses. Intermittent bouts of intestinal obstruction, hypoproteinemia, and failure to thrive are common. Encopresis is rare.

On digital rectal examination, the anal canal and rectum are devoid of fecal material despite obvious retained stool on abdominal examination or radiographs. If the aganglionic segment is short, there may be a gush of flatus and stool as the finger is withdrawn.

**DISORDERS OF THE COLON**

**CONGENITAL AGANGLONIC MEGACOLON (HIRSCHSPRUNG DISEASE)**

**General Considerations**

Hirschsprung disease results from an absence of ganglion cells in the mucosal and muscular layers of the colon. Neural crest cells fail to migrate into the mesodermal layers of the gut during gestation, possibly secondary to abnormal end-organ cell surface receptors or local deficiency of nitric oxide synthesis. The absence of ganglion cells results in failure of the colonic muscles to relax in front of an advancing bolus. In 80% of individuals, aganglionosis is restricted to the rectosigmoid colon (short-segment disease); in 15%–20%, aganglionosis extends proximal to the sigmoid colon (long-segment disease); and in about 5%, aganglionosis affects the entire large intestine (total colonic aganglionosis). Segmental aganglionosis is possible but rare.

The aganglionic segment has normal or slightly narrowed caliber with dilation of the normal colon proximal to the obstructing aganglionic segment. The mucosa of the dilated colonic segment may become thin and inflamed, causing diarrhea, bleeding, and protein loss (enterocolitis).

A familial pattern has been described, particularly in total colonic aganglionosis. The incidence of Hirschsprung disease is 1 in 5000 live births; it is four times more common in boys than girls. A chromosomal abnormality is present in approximately 12% of individuals with Hirschsprung disease. Mutations in the ret proto-oncogene have been identified in about 15% of nonsyndromic cases. The most common chromosomal abnormality associated with Hirschsprung disease is Down syndrome; 2%–10% of all individuals with Down syndrome may have Hirschsprung disease.

**Clinical Findings**

**A. Symptoms and Signs**

Failure of the newborn to pass meconium, followed by vomiting, abdominal distention, and reluctance to feed, suggests the diagnosis of Hirschsprung disease. Most children with Hirschsprung disease do not pass stool in the first 24 hours of their life. Enterocolitis manifest by fever, explosive diarrhea, and prostration is reported in approximately 50% of affected newborns. Enterocolitis may lead to inflammatory and ischemic changes in the colon, with perforation and sepsis. In some patients, especially those with short segments involved, symptoms are not obvious at birth. In later infancy, alternating obstipation and diarrhea predominate. The older child is more likely to have constipation alone. Symptoms can include foul-smelling or ribbon-like stools, a distended abdomen with prominent veins and visible peristaltic waves with palpable fecal masses. Intermittent bouts of intestinal obstruction, hypoproteinemia, and failure to thrive are common. Encopresis is rare.

On digital rectal examination, the anal canal and rectum are devoid of fecal material despite obvious retained stool on abdominal examination or radiographs. If the aganglionic segment is short, there may be a gush of flatus and stool as the finger is withdrawn.

Infants of diabetic mothers may have similar symptoms, and in this setting small left colon syndrome should be suspected. Meglumine diatrizoate (Gastrografin) enema is both diagnostic and therapeutic in small left colon syndrome as it reveals a meconium plug in the left colon, which is often
passed during the diagnostic radiograph. The left colon is narrow but usually functional.

**B. Laboratory Findings**

Ganglion cells are absent in both the submucosal and muscular layers of involved bowel. Special stains may show nerve trunk hypertrophy and increased acetylcholinesterase activity. Ganglionated bowel above the aganglionic segment is sometimes found to contain more than normal numbers of ganglion cells in abnormal locations (neuronal dysplasia).

**C. Imaging**

Plain abdominal radiographs may reveal dilated proximal colon and absence of gas in the pelvic colon. Barium enema using a catheter without a balloon and with the tip inserted barely beyond the anal sphincter usually demonstrates a narrow distal segment with a sharp transition to the proximal dilated (normal) colon. Transition zones may not be seen in neonates since the normal proximal bowel has not had time to become dilated. Retention of barium for 24–48 hours is not diagnostic of Hirschsprung disease in older children as it typically occurs in retentive constipation as well.

**D. Special Examinations**

Rectal manometric testing reveals failure of rectoanal inhibitory reflex (RAIR), relaxation of the internal anal sphincter after distention of the rectum in all patients with Hirschsprung disease, regardless of the length of the aganglionic segment. In occasional patients, a nonrelaxing internal anal sphincter may control symptoms. This condition is often called “ultrashort segment Hirschsprung disease.”

**Differential Diagnosis**

Hirschsprung disease accounts for 15%–20% of cases of neonatal intestinal obstruction. It must be differentiated from the small left colon syndrome by biopsy. In childhood, Hirschsprung disease must be differentiated from retentive constipation, hypothyroidism, intestinal pseudo-obstruction, and other motility disorders. In older infants and children, it can also be confused with celiac disease because of the striking abdominal distention and failure to thrive.

**Treatment & Prognosis**

Treatment is surgical. Depending on the child’s size and state of health, a diverting colostomy (or ileostomy) may be performed or the surgeon may undertake a primary repair. In unstable infants, resection of the aganglionic segment may be postponed. At the time of definitive surgery, the transition zone between ganglionated and nonganglionated bowel is identified. Aganglionic bowel is resected, and a pull-through of ganglionated bowel to the preanal rectal remnant is made. The three most commonly performed repairs are the Swenson, Duhamel, and Soave procedures. Several surgical techniques, including laparoscopic pull-through, are in use. In children with ultrashort segment disease, an internal anal sphincter myotomy, or botulinum toxin injection of the internal anal sphincter may control symptoms.

Complications after surgery include fecal retention, fecal incontinence, anastomotic breakdown, or anastomotic stenosis. Postoperative obstruction may result from inadvertent retention of a distal aganglionic colon segment or postoperative destruction of ganglion cells secondary to vascular impairment. Neuronal dysplasia of the remaining bowel may produce a pseudo-obstruction syndrome. Enterocolitis occurs postoperatively in 15% of patients.

**CONSTITUTION**

Chronic constipation in childhood is defined as two or more of the following characteristics for 2 months: (1) fewer than three bowel movements per week; (2) more than one episode of encopresis per week; (3) impaction of the rectum with stool; (4) passage of stool so large it obstructs the toilet; (5) retentive posturing and fecal withholding; and (6) pain with defecation. Retention of feces in the rectum can result in overflow incontinence (encopresis) in 60% of children with constipation. Most constipation in childhood is a result of voluntary or involuntary retentive behavior (chronic retentive constipation). About 2% of healthy primary school children have chronic retentive constipation. The ratio of males to females may be as high as 4:1.

**Clinical Findings**

Infants younger than 3 months often grunt, strain, and turn red in the face while passing normal stools. Failure to appreciate this normal developmental pattern may lead to the unwise use of laxatives or rectal stimulation. Infants and children may, however, develop the ability to ignore the sensation of rectal fullness and retain stool. Many factors reinforce this behavior, which results in impaction of the rectum and overflow incontinence. Among these are painful defecation; skeletal muscle weakness; psychological issues, especially those relating to control and authority; modesty and distaste for school bathrooms; medications; and other
The dilated rectum gradually becomes less sensitive to fullness, thus perpetuating the problem.

**Differential Diagnosis**

One must distinguish between chronic retentive constipation from Hirschsprung disease as summarized in Table 21–3.

**Treatment**

In children with poor diets increased intake of high-residue foods such as bran, whole wheat, fruits and vegetables, and water may be sufficient therapy in mild constipation. If diet change alone is ineffective, medications may be required. Polyethylene glycol solution (MiraLax), 0.8–1 g/kg/day, lactulose 1–2 g/kg/day, and milk of magnesia for 2–5 years old: 400–1200 mg/day, 6–11 years old: 1200–2400 mg/day are safe stool softeners in infants and children. Stimulant laxatives such as Senna or Bisacodyl can be considered as an additional or second-line treatment. A recent study showed lubiprostone (Amitiza) was efficacious and well tolerated in children and adolescents with functional constipation. Lubiprostone is a prostone that, acting locally as a specific activator of chloride channel protein-2 in the GI epithelium, promotes intestinal secretion of chloride ions and fluid, enhancing GI motility. If encopresis is present, treatment should start with relieving fecal impaction. Disimpaction can be achieved in several ways, including medications such as saline enemas, and nonabsorbable osmotic agents such as polyethylene glycol (MiraLax, 1 g/kg/day) and milk of magnesia (1–2 mL/kg/day). Effective stool softeners should thereafter be given regularly in doses sufficient to induce very soft daily bowel movements. After several weeks to months of regular soft stools, stool softeners can be tapered and stopped. Mineral oil should not be given to nonambulatory infants, physically handicapped or bed-bound children, or any child with GE reflux. Aspiration of mineral oil may cause lipid pneumonia. Recurrence of encopresis is common and should be treated promptly with a short course of stimulant laxatives or an enema. Psychiatric consultation may be needed.

change alone is ineffective, medications may be required. Polyethylene glycol solution (MiraLax), 0.8–1 g/kg/day, lactulose 1–2 g/kg/day, and milk of magnesia for 2–5 years old: 400–1200 mg/day, 6–11 years old: 1200–2400 mg/day are safe stool softeners in infants and children. Stimulant laxatives such as Senna or Bisacodyl can be considered as an additional or second-line treatment. A recent study showed lubiprostone (Amitiza) was efficacious and well tolerated in children and adolescents with functional constipation. Lubiprostone is a prostone that, acting locally as a specific activator of chloride channel protein-2 in the GI epithelium, promotes intestinal secretion of chloride ions and fluid, enhancing GI motility. If encopresis is present, treatment should start with relieving fecal impaction. Disimpaction can be achieved in several ways, including medications such as saline enemas, and nonabsorbable osmotic agents such as polyethylene glycol (MiraLax, 1 g/kg/day) and milk of magnesia (1–2 mL/kg/day). Effective stool softeners should thereafter be given regularly in doses sufficient to induce very soft daily bowel movements. After several weeks to months of regular soft stools, stool softeners can be tapered and stopped. Mineral oil should not be given to nonambulatory infants, physically handicapped or bed-bound children, or any child with GE reflux. Aspiration of mineral oil may cause lipid pneumonia. Recurrence of encopresis is common and should be treated promptly with a short course of stimulant laxatives or an enema. Psychiatric consultation may be needed.
indicated for patients with resistant symptoms or severe emotional disturbances.

**ANAL FISSURE**

Anal fissure is a slit-like tear in the squamous epithelium of the anus, which usually occurs secondary to the passage of large, hard fecal masses, typically at the superior and inferior aspects of the anus. Anal stenosis, anal crypt abscess, and trauma can be contributory factors. Sexual abuse must be considered in children with large, irregular, or multiple anal fissures. Anal fissures may be the presenting sign of Crohn disease in older children.

The infant or child with anal fissure typically cries with defecation and will try to hold back stools. Sparse, bright red bleeding is seen on the outside of the stool or on the toilet tissue following defecation. The fissure can often be seen if the patient is examined in a knee-chest position with the buttocks spread apart. When a fissure cannot be identified, it is essential to rule out other causes of rectal bleeding such as juvenile polyp, perianal inflammation due to group A β-hemolytic streptococcus, or inflammatory bowel disease (IBD). Anal fissures should be treated promptly to break the constipation, fissure, pain, retention, and constipation cycle. A stool softener should be given. Warm Sitz baths after defecation may be helpful. Rarely, silver nitrate cauterization or surgery is indicated. Anal surgery should be avoided in infants with Crohn disease because of the high risk of recurrence and progression after surgery.

**CONGENITAL ANORECTAL ANOMALIES**

**1. Anterior Displacement of the Anus**

Anterior displacement of the anus is a common anomaly of infant girls. Its usual presentation in infants is constipation and straining with stool. On physical examination, the anus looks normal but is ventrally displaced, located close to the vaginal fourchette (in females) or to the base of the scrotum (in males). The diagnosis is made in girls if the distance from the vaginal fourchette to the center of the anal opening is less than 34% of the total distance from fourchette to coccyx. In boys, the diagnosis is made if the distance from the base of the scrotum to the anal aperture is less than 46% of the total distance from scrotum to coccyx. Often on internal digital examination a posterior “rectal shelf” will be appreciated. In severe anterior displacement, when the anal opening is located less than 10% of the distance from the vaginal fourchette to the coccyx, the anal sphincter muscle may not completely encircle the anal opening and severe obstipation similar to that seen in imperforate anus may occur. Indeed, extreme anterior displacement of the anus may be a form of imperforate anus. Surgery is not needed in most cases. Stool softeners or occasional glycerin suppositories usually relieve straining. This problem improves significantly by age 3–4 years as normal toddler lordosis disappears.

**2. Anal Stenosis**

Anal stenosis usually presents in the newborn period. The anal aperture may be very small and filled with a dot of meconium. Defecation is difficult, with ribbonlike stools, blood and mucus per rectum, fecal impaction, and abdominal distention. Anal stenosis occurs in about 3 of 10,000 live births, with slightly more males affected. Anal stenosis may not be apparent at birth because the anus looks normal. Rectal bleeding in a straining infant often leads to a rectal examination, which reveals a tight ring in the anal canal. Dilation of the anal ring is usually curative but may have to be repeated daily for several weeks.

**3. Imperforate Anus**

Imperforate anus typically develops during the fifth to seventh week of pregnancy and occurs in 1 of 5000 live births, slightly more common males. Almost 50% of babies with imperforate anus have additional defects, often in association with a particular syndrome.

Defects are generally classified as low (rectoperineal malformation) where the rectum may not connect to the anus, a membrane may be present over the anal opening, or the anal opening may be narrow or misplaced. A high lesion is classified where the rectum may connect to part of the urinary tract or the reproductive system through a fistula. Infants with low imperforate anus fail to pass meconium. There may be a greenish bulging membrane obstructing the anal aperture. Perforation of the anal membrane is a relatively simple surgical procedure. A skin tag shaped like a “bucket handle” is seen on the perineum of some males below which a stenotic aperture can be seen. The aperture is sometimes surrounded by normal anal musculature, but in many cases the aperture is a rectoperineal fistula and the anal musculature is displaced posteriorly or is absent. Eighty to 90% of patients with low imperforate anus are continent after surgery. In high imperforate anus, physical examination usually shows no anal musculature. There may be a rectoperineal, rectovesicular, rectourethral, or rectovaginal fistula; hypoplastic buttocks; cloacal anomalies; and sometimes evidence of distal neurologic deficit. It is critical in these cases to fully evaluate the complex anatomy and neurologic function before attempting corrective surgery. A diverting colostomy is usually performed to protect the urinary tract and relieve obstruction. After reparative surgery, only 30% of patients with high imperforate anus achieve fecal continence.
CLOSTRIDIUM DIFFICILE INFECTION
IN CHILDREN

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- *C. difficile* in children leads to a spectrum of clinical disease, from asymptomatic colonization to severe pseudomembranous colitis with fever, severe abdominal pain, and bloody diarrhea.
- Risk factors for *C. difficile* disease include previous antibiotic use and a variety of chronic diseases, including immunodeficiency, cystic fibrosis, Hirschsprung disease, IBD, oncology patients, and solid-organ transplant recipients.
- Community-acquired *C. difficile* disease in healthy hosts is increasing in incidence.

Pathogenesis

*C. difficile* is a spore-forming gram-positive bacillus that causes human disease via the secretion of enterotoxins that cause necrotizing inflammation of the colon. Interestingly, asymptomatic *C. difficile* colonization of the human GI tract occurs commonly in infants and can occur in older children and adults as well. To some extent, *C. difficile* may reside in balance with the constituent intestinal microbiome in a healthy host. Disruption of normal commensal intestinal bacteria or interruption of host immune defense, via intestinal injury or host immune suppression, then appears to give *C. difficile* a potential foothold in the human gut where it can lead to disease. Hospitalization is a critical risk factor for *C. difficile* disease. Additional risk factors in children include previous antibiotic use and a variety of chronic diseases including IBD, cystic fibrosis, Hirschsprung disease, solid-organ transplant recipients, oncology patients, and immunodeficient hosts. For reasons that are incompletely understood, community-acquired symptomatic *C. difficile* infection in healthy children is increasing in incidence.

In recent years there has been an alarming increase in the incidence, morbidity, and mortality of *C. difficile* reported in Europe, Canada, and the United States. At least a portion of this increase seems to be due to the expansion of a new strain of *C. difficile*, identified as the North American Pulsed Field type 1 (NAP1) *C. difficile*, which has been found to have increased toxin production, sporulation, and antibiotic resistance. Surveillance from children’s hospitals seems to mirror the increase in incidence of *C. difficile* in adults but not necessarily the increase in morbidity and mortality. Pediatric hospitalizations in the United States due to *C. difficile* have almost doubled between 1997 and 2006. The NAP1 strain was identified in 19% of *C. difficile* isolates in a recent pediatric study.

Clinical Findings

*C. difficile* disease in children represents a spectrum of clinical symptoms, ranging from asymptomatic colonization to persistent, watery diarrhea to pseudomembranous colitis. Recognizing that antibiotic exposure remains a critical risk factor, the onset of colitis ranges from 1 to 14 days after initiation of antibiotic therapy to as many as 30 days after antibiotics have been discontinued. Clindamycin was one of the first antibiotics associated with pseudomembranous colitis, but all antibiotics are now recognized to be potential causes, although erythromycin seems less likely than most. In pediatric patients, amoxicillin and cephalosporins are commonly associated with pseudomembranous enterocolitis, probably because of their widespread use.

The patient with pseudomembranous colitis characteristically has fever, abdominal distention, tenesmus, diarrhea, and generalized abdominal tenderness. Chronic presentations with low-grade fever, diarrhea, and abdominal pain have been described. Diarrheal stools contain sheets of neutrophils and sometimes gross blood. Plain abdominal radiographs show a thickened colon wall and ileus. Endoscopically, the colon appears to be covered by small, raised white plaques (pseudomembranes) with areas of apparently normal bowel in between (Figure 21–5). Biopsy specimens show “exploding crypts or volcano lesion”—an eruption of white cells that appears to be shooting out of affected crypts. Stool cultures often show overgrowth of *Staphylococcus aureus*, which is probably an opportunistic organism growing in the necrotic tissue. *C. difficile* can be cultured in specialized laboratories. Identification of stool toxins is the usual method of diagnosis. Use of real-time polymerase chain reaction (PCR) for toxin identification has been replacing more traditional enzyme immunoassay (EIA) methods of stool toxin detection, because of improved sensitivity. Interpretation of *C. difficile* diagnostic testing in infants remains controversial because asymptomatic colonization is well recognized in the first year of life.

Treatment

Standard treatment of pseudomembranous colitis consists of stopping antibiotics and instituting therapy with oral metronidazole (30 mg/kg/day) or vancomycin (30–50 mg/kg/day). Vancomycin is many times more expensive than metronidazole and no more efficacious. Metronidazole can be given intravenously in patients with vomiting or
ileus. With increasing virulence and antibiotic resistance being reported, alternative therapies, such as rifaximin and nitazoxanide, are being used and show similar response rates as oral vancomycin. Relapse occurs after treatment in 10%–50% of patients because of exsporulation of residual spores in the colon. Spores are very hardy and may remain viable on inanimate surfaces for up to 12 months. Retreatment with the same antibiotic regimen is usually effective, but multiple relapses are possible and may be a significant management problem. Adjunctive strategies, such as *Saccharomyces boulardii* probiotic therapy, cholestyramine as a toxin-binder, and pulsed courses of antibiotics have been used for refractory disease. Fecal bacteriotherapy, known popularly as *fecal transplantation*, is now a widely accepted and nearly 100% effective treatment for the treatment of recurrent *C difficile* infection in adults but experience remains limited in children.

**DISORDERS OF THE PERITONEAL CAVITY**

**PERITONITIS**

Primary bacterial peritonitis accounts for less than 2% of childhood peritonitis. The most common causative organisms are *Escherichia coli*, other enteric organisms, hemolytic streptococci, and pneumococci. Primary peritonitis occurs in patients with splenectomy, splenic dysfunction, or ascites (nephrotic syndrome, advanced liver disease, kwashiorkor). It can also occur in infants with pylonephritis or pneumonia.

Secondary peritonitis is much more common. It is associated with peritoneal dialysis, abdominal trauma, or ruptured viscus. The organisms associated with secondary peritonitis vary with the cause. Organisms such as *Staphylococcus epidermidis* and *Candida* may cause secondary peritonitis in patients receiving peritoneal dialysis. Multiple enteric organisms may be isolated after abdominal injury, bowel perforation, or ruptured appendix. Intra-abdominal abscesses may form in pelvic, subhepatic, or subphrenic areas.

Symptoms of peritonitis include abdominal pain, fever, nausea, vomiting, acidosis, and shock. The abdomen is tender, rigid, and distended, with involuntary guarding. Bowel sounds may be absent. Most peritonitis is an acute medical emergency. In patients receiving peritoneal dialysis, peritonitis can be a chronic infection causing milder symptoms.

Leukocyte count is high initially (> 20,000/μL) with a predominance of immature forms, and later it may fall to neutropenic levels, especially in primary peritonitis. Abdominal imaging can confirm the presence of ascites. Bacterial peritonitis should be suspected if paracentesis fluid contains more than 500 leukocytes/μL or more than 32 mg/dL of lactate; if it has a pH less than 7.34; or if the pH is over 0.1 pH unit less than arterial blood pH. Diagnosis is made by Gram stain and culture, preferably of 5–10 mL of fluid for optimal yield. The blood culture is often positive in primary peritonitis.

Antibiotic treatment and supportive therapy for dehydration, shock, and acidosis are indicated. Surgical treatment of the underlying cause of secondary peritonitis is critical. Removal of infected peritoneal dialysis catheters in patients with secondary peritonitis is sometimes necessary and almost always required if *Candida* infection is present.

**CHYLOUS ASCITES**

Neonatal chylous ascites may be due to congenital infection or developmental abnormality of the lymphatic system (intestinal lymphangiectasia). If the thoracic duct is involved,
chylothorax may be present. Later in life, chylous ascites may result from congenital lymphangiectasia, retroperitoneal or lymphatic tumors, peritoneal bands, abdominal trauma, intestinal malrotation or infection, or it may occur after cardiac or abdominal surgery.

### Clinical Findings

#### A. Symptoms and Signs

Both congenital and acquired lymphatic obstructions cause chylous ascites, diarrhea, and failure to thrive. The abdomen is distended, with a fluid wave and shifting dullness. Unilateral or generalized peripheral edema may be present.

#### B. Laboratory Findings

Laboratory findings include hypoalbuminemia, hypogammaglobulinemia, and lymphopenia. Ascitic fluid contains lymphocytes and has the biochemical composition of chyle if the patient has just been fed; otherwise, it is indistinguishable from ascites secondary to cirrhosis.

### Differential Diagnosis

Chylous ascites must be differentiated from ascites due to liver disease and in the older child, from constrictive pericarditis, chronically elevated right heart pressure, malignancy, infection, or inflammatory diseases causing lymphatic obstruction. In the newborn, urinary ascites from anatomic abnormalities of the kidney or collecting system must be considered. A simple test to diagnose urinary ascites is a urea nitrogen or creatinine concentration of abdominal fluid. Neither of these is present in chylous or hepatic ascites.

### Complications & Sequelae

Chylous ascites caused by intestinal lymphatic obstruction is associated with fat malabsorption and protein loss. Intestinal loss of albumin may lead to edema. Rapidly accumulating chylous ascites may cause respiratory complications. The primary infections and malignancies causing chylous ascites may be life threatening.

### Treatment & Prognosis

Little can be done to correct congenital abnormalities due to hypoplasia, aplasia, or ectasia of the lymphatics unless they are surgically resectable. More recently, somatostatin and fibrin glue have been tried with varying success. Treatment is supportive, consisting mainly of a high-protein diet and careful attention to infections. Shunting of peritoneal fluid into the venous system is sometimes effective. A fat-free diet supplemented with medium-chain triglycerides decreases the formation of chylous ascites. Total parenteral nutrition (TPN) may rarely be necessary. Infusions of albumin generally provide only temporary relief and are rarely used for chronic management. In the neonate, congenital chylous ascites may spontaneously disappear following one or more paracenteses and a medium-chain triglyceride diet.

---

**GASTROINTESTINAL TUMORS & MALIGNANCIES**

**JUVENILE POLYPS**

Juvenile polyps belong to the hamartomatous category of polyps and are usually pedunculated (with a stalk) and solitary (Figure 21–6). The head of the polyp is composed of hyperplastic glandular and vascular elements, often with cystic transformation. Juvenile polyps are benign, and 80% occur in the rectosigmoid. These are the most common type of intestinal polyps in children, accounting for more than...
90% of pediatric polyps. Their incidence is highest between ages 3 and 5 years. They are rare before age 1 year and usually occur before age 10. The painless passage of small amounts of bright red blood with mucus on a normal or constipated stool is the most frequent manifestation. Abdominal pain is rare, but low-lying polyps may prolapse during defecation. Colonoscopy is diagnostic and therapeutic when polyps are suspected. After removal of an isolated polyp by electrocautery, nothing further should be done if histologic findings confirm the diagnosis. There is a slight risk of developing further juvenile polyps. It is generally believed that the presence of one or a few juvenile polyps does not increase risk of colon cancer, and does not warrant surveillance necessarily, but no evidence-based guidelines exist for this population. Other polyposis syndromes are summarized in Table 21–4. The presence of any polyp should prompt a careful clinical and family history for polyps or cancer (especially at an early age), and if positive, consideration for genetic screening and appropriate counseling.

Rarely, many juvenile polyps may be present in the colon, causing anemia, diarrhea with mucus, and protein loss. An individual may be diagnosed with juvenile polyposis syndrome (JPS) if there are more than five juvenile polyps in the colon, multiple juvenile polyps elsewhere in the GI tract, or any number of juvenile polyps with a family history of JPS. JPS carries an increased risk of colorectal cancer, and a need for careful surveillance. Approximately half have a positive family history, and the other half with a germline mutations are found in SMAD4 or BMPRIA. Other types of hamartomatous polyp syndromes include Peutz-Jeghers syndrome and the PTEN hamartoma tumor syndrome. Peutz-Jeghers syndrome is associated with polyps commonly in the small intestine but can also been seen in the colon, stomach, and in other organs. There is a distinctive mucocutaneous pigmentation (freckling) that appears early on but can disappear by age 5, along the vermilion border of the lips, buccal mucosa, and hands and feet. Besides the higher risk of both GI and non-GI malignancies, routine cancer surveillance is necessary. Most will have GI symptoms before 20 years

<sup>a</sup>Autosomal dominant.
<sup>b</sup>Autosomal recessive.
of age, and 50% will develop intussusception at some point in their lifetime. PTEN hamartoma syndrome involves a spectrum of hamartomatous conditions that are associated with mutations in the PTEN gene. This includes nearly all Cowden syndrome and some Bannayan-Riley Ruvalcaba syndrome and Proteus syndrome. Besides hamartomas and other benign tumors throughout the body, there is an increased risk of intestinal and extraintestinal cancers. Clinical practice guidelines continue to evolve, and many follow those from the National Comprehensive Cancer Network: https://www.nccn.org/professionals/physician_gls/default.aspx.

Familial polyposis syndromes are at greater risk. A history of colon cancer, chronic ulcerative colitis (UC), or both is greater in pediatric rectal cancer. Children with a family history of colorectal cancer have a higher risk of developing colorectal polyps and adenocarcinoma. This risk is most pronounced for familial adenomatous polyposis (FAP) and hereditary nonpolyposis colorectal cancer (HNPCC). FAP is caused by mutations in the APC gene, which are inherited in an autosomal dominant pattern. HNPCC is caused by mutations in one of several DNA mismatch repair genes, which are also inherited in an autosomal dominant pattern.

CANCERS OF THE ESOPHAGUS, SMALL BOWEL, & COLON

Esophageal cancer is rare in childhood. Cysts, leiomyomas, and hamartomas predominate. Caustic injury to the esophagus increases the very long-term risk of squamous cell carcinoma. Chronic peptic esophagitis is associated with Barrett esophagus, a precancerous lesion. Simple GE reflux in infancy without esophagitis is not a risk for cancer of the esophagus.

The most common gastric or small bowel cancer in children is lymphoma or lymphosarcoma. Intermittent abdominal pain, abdominal mass, intussusception, or a celiac-like picture may be present. Carcinoid tumors are usually benign and most often an incidental finding in the appendix. Metastasis is rare. The carcinoid syndrome (flushing, sweating, hypertension, diarrhea, and vomiting), associated with serotonin secretion, only occurs with metastatic carcinoid tumors.

Adenocarcinoma of the colon is rare in childhood, representing only 1% of pediatric malignancies. The low 5-year survival rate relates to the nonspecificity of presenting complaints and the large percentage of aggressive histology with poorly, or undifferentiated types. This disparity may be greater in pediatric rectal cancer. Children with a family history of colon cancer, chronic ulcerative colitis (UC), or familial polyposis syndromes are at greater risk.

MESENERIC CYSTS

Mesenteric and omental cysts are rare intra-abdominal masses in children. These cysts may be small or large, single or multiloculated. They are thin-walled and contain serous, chylous, or hemorrhagic fluid. They are commonly located in the small bowel mesentery but are also found in the mesocolon. Most mesenteric cysts cause no symptoms and are found incidentally. Traction on the mesentery may lead to colicky abdominal pain, which can be mild and recurrent but may appear acutely with vomiting. Volvulus may occur around a cyst, and hemorrhage into a cyst may be mild or hemodynamically significant. A rounded mass can occasionally be palpated or seen on radiograph displacing adjacent intestine. Abdominal ultrasonography is usually diagnostic. Surgical removal is indicated. Malignant transformation of mesenteric cysts has been reported in adults, and therefore surgical removal is indicated even in asymptomatic cases.

INTESTINAL HEMANGIOMAS & VASCULAR MALFORMATIONS

Hemangiomas and vascular malformations of the GI tract are uncommon causes of GI bleeding in children and adults. Like their skin counterparts, intestinal hemangiomas are typically not present at birth and then appear in the first 2 months of life, undergoing a rapidly proliferating growth phase during the first year, during which they are most likely to cause symptomatic bleeding, before involution thereafter. Vascular malformations include capillary, arterial, venous, and mixed lesions, and are present from birth with risk of bleeding throughout life. The physically largest subtype of vascular lesion is the cavernous malformation, which may protrude into the lumen as a polyoid lesion or may invade the intestine from mucosa to serosa.

Clinical Presentation

Intestinal vascular lesions are most often found in the small bowel. These lesions may cause acute or occult blood loss or may present as intussusception, intestinal narrowing, or intramural hematoma. Thrombocytopenia and consumptive coagulopathy are occasional complications of larger hemangiomas during their rapid proliferation phase. Intestinal vascular lesions are usually found in isolation, but associated syndromes include the blue rubber bleb nevus syndrome, the Osler-Rendu-Weber syndrome, and the Klippel-Trenaunay-Weber syndrome. The etiology of GI bleeding can be elusive, particularly when bleeding is occult. The physical examination is typically not helpful unless there are other skin
hemangiomas present in the young child that may point to an intestinal hemangioma. Vascular protocols with CT or magnetic resonance imaging (MRI) may identify larger vascular lesions. Endoscopic techniques remain crucial to the diagnosis of intestinal vascular lesions. Video capsule endoscopy and small bowel enteroscopy techniques have allowed for diagnosis and potential therapy of small bowel vascular lesions that were previously inaccessible using conventional endoscopy.

**Treatment**

Vascular malformations of the skin and liver have been treated medically with corticosteroids, propranolol, sirolimus, angiotensin converting enzyme inhibitors, interferon, and vincristine. There is relatively little experience using these medical techniques for intestinal hemangiomas. Endoscopic techniques for treatment of vascular lesions include banding, submucosal injections of sclerosants, and electrocautery methods. Vascular embolization is a consideration for rapid blood loss in the setting of gastrointestinal vascular malformations. Finally, surgical resection of the vascular lesion and surrounding bowel may be required for lesions in the mid-small bowel that are not accessible by endoscopy or for large lesions that are not amenable to endoscopic therapies.

**ACUTE DIARRHEA**

Viruses are the most common cause of acute gastroenteritis in developing and developed countries. Bacterial and parasitic enteric infections are discussed in Chapters 42 and 43. Of the viral agents causing enteric infection, rotavirus, a 67-nm double-stranded RNA virus with at least eight serotypes, is the most commonly identified. As with most viral pathogens, rotavirus affects the small intestine, causing voluminous watery diarrhea without leukocytes or blood. In the United States, rotavirus primarily affects infants between 3 and 15 months of age. The peak incidence in the United States is in the winter with sporadic cases occurring at other times. The virus is transmitted via the fecal-oral route and survives for hours on hands and for days on environmental surfaces.

1. **Rotavirus Infection**

The incubation period for rotavirus is 1–3 days. Symptoms caused by rotavirus are similar to other viral pathogens. Vomiting is the first symptom in 80%–90% of patients, followed within 24 hours by low-grade fever and watery diarrhea. Diarrhea usually lasts 4–8 days but may last longer in young infants or immunocompromised patients. Rotavirus cannot be definitively diagnosed on clinical grounds alone. Rotavirus antigens can be identified in stool or virus can be seen by scanning electron microscopy. The specific identification of rotavirus is not required in every case, however, as treatment is nonspecific. Additional laboratory testing is also generally unnecessary, but, when obtained, it will usually show a normal white blood cell count. Hyper- or hyponatremia may occur with dehydration. Metabolic acidosis can occur from bicarbonate loss in the stool, ketosis from poor intake, and in severe cases lactic acidemia occurs from hypotension and hypoperfusion. Stools do not typically contain blood or white blood cells.

As with most other viral causes of acute diarrhea, treatment is nonspecific and supportive. Replacement of fluid and electrolyte deficits, along with ongoing losses, especially in small infants is necessary. The use of oral rehydration solutions is appropriate in most cases (oral and intravenous therapies are discussed in Chapter 23). The use of clear liquids or hypocaloric (dilute formula) diets for more than 48 hours is not advisable. Early initiation of refeeding is recommended. Intestinal lactase levels may be reduced during rotavirus infection, and brief use of a lactose-free diet may hasten resolution of diarrhea but is not critical to successful recovery in healthy infants. Reduced fat intake during recovery may decrease nausea and vomiting.

Antidiarrheal medications are ineffective (kaolin-pectin combinations) and in some circumstances can be dangerous (loperamide, tincture of opium, diphenoxylate with atropine). Loperamide has been recommended (with caution) in afebrile adults without dysentery to shorten duration of diarrhea. Bismuth subsalicylate preparations may reduce stool volume but are generally not recommended, especially in young children due to the salicylate component and risk of Reye syndrome. Oral immunoglobulin or specific antiviral agents have occasionally been useful in limiting duration of disease in immunocompromised patients.

Most children are infected with rotavirus more than once, with the first infection being the most severe. Some protective immunity is imparted by the first infection. Prevention of infection occurs primarily by good hygiene and prevention of fecal-oral contamination. As treatment for rotavirus is nonspecific, prevention of illness is critical.
The American Academy of Pediatrics issued guidelines in January 2007 recommending the routine use of bovine-based pentavalent rotavirus vaccine to be given orally to infants at 2, 4, and possibly 6 months of age, depending on which vaccine is used.

2. Other Viral Infections Causing Acute Diarrhea

Other viral pathogens causing diarrhea in children can be identified in stool by electron microscopy, viral culture, or enzyme-linked immunoassay. Depending on the geographic location, enteric adenoviruses (serotypes 40 and 41) or caliciviruses are the next most common viral pathogens in infants. The symptoms of enteric adenovirus infection are similar to those of rotavirus, but infection is not seasonal and the duration of illness may be longer. The Norwalk agent (now called norovirus), a calicivirus, is a small RNA virus that mainly causes vomiting but can also cause diarrhea in older children and adults, usually in common source outbreaks. The duration of symptoms is short, usually 24–48 hours. Other potentially pathogenic viruses include astroviruses, corona-like viruses, and other small round viruses.

Cytomegalovirus rarely causes diarrhea in immunocompetent children but may cause erosive and severe enterocolitis in immunocompromised hosts. Cytomegalovirus enteritis is particularly common after solid-organ and bone marrow transplant and in the late stages of human immunodeficiency virus (HIV) infection.

Probiotics are, at best, modestly effective in treating acute viral gastroenteritis in healthy children and should be used with extreme caution in immunocompromised, chronically debilitated, or seriously ill children.

CHRONIC DIARRHEA

Bowel habits are variable, making the specific diagnosis of chronic diarrhea difficult. Some healthy infants may have five to eight stools daily. A gradual or sudden increase in the number and volume of stools to more than 15 g/kg/day combined with an increase in fluidity should raise a suspicion that an organic cause of chronic diarrhea is present. Diarrhea may result from (1) interruption of normal cell transport processes for water, electrolytes, or nutrients; (2) decrease in surface area available for absorption secondary to shortened bowel or mucosal disease; (3) increase in intestinal motility; (4) increase in unabsorbable, osmotically active molecules in the intestinal lumen; (5) increase in intestinal permeability, leading to increased loss of water and electrolytes; and (6) stimulation of enterocyte secretion by toxins or cytokines. The most common entities causing chronic diarrhea are listed as follows. Malabsorption syndromes, which also cause chronic or recurrent diarrhea, are considered separately.

1. Causes of Chronic Diarrhea

A. Antibiotic Therapy

Acute and chronic diarrhea is reported in up to 60% of children receiving antibiotics. Only a small fraction of these patients have C. difficile-related pseudomembranous enterocolitis. Eradication of normal gut flora and overgrowth of other organisms may cause antibiotic-associated diarrhea. Most antibiotic-associated diarrhea is watery, is not associated with systemic symptoms, and decreases when antibiotic therapy is stopped. Data are mixed regarding the use of probiotics, though some suggest their use may decrease the incidence and severity of this diarrhea by helping to restore intestinal microbial balance.

B. Extraintestinal Infections

Infections of the urinary tract and upper respiratory tract (especially otitis media) are at times associated with diarrhea, though the mechanism is incompletely understood. Antibiotic treatment of the primary infection, toxins released by infecting organisms, and local irritation of the rectum (in patients with bladder infection) may play a role.

C. Malnutrition

Malnutrition is associated with an increased frequency of enteral infections. Decreased bile acid synthesis, decreased pancreatic enzyme output, decreased disaccharidase activity, altered motility, and changes in the intestinal flora all may contribute to diarrhea. In addition, severely malnourished children are at higher risk of enteric infections because of depressed cellular and humoral immune functions. Protein-calorie malnutrition can result in villous atrophy, and represent an important cause of malabsorption.

D. Diet and Medications

Relative deficiency of pancreatic amylase in young infants causes osmotic diarrhea after starchy foods. Fruit juices, especially those high in fructose or sorbitol, produce diarrhea because these osmotically active sugars are poorly absorbed. Intestinal irritants (spices and foods high in fiber) and histamine-containing or histamine-releasing foods...
(eg, citrus fruits, tomatoes, fermented cheeses, red wines, and scombroid fish) may also cause diarrhea.

FODMAPs (Fermentable, Oligo-, Di-, Mono-saccharides And Polyols) are a group of poorly absorbed short-chain carbohydrates that are not uncommonly malabsorbed. Lactose and fructose are classic examples of FODMAPs. Malabsorption of foods higher in FODMAPs can cause symptoms of chronic intermittent diarrhea. It has been implicated as a cause of diarrhea and other symptoms (bloating, gasiness, abdominal pain) in certain individuals with a prior diagnosis of irritable bowel syndrome. Removal of certain FODMAPs from the diet may improve symptoms.

Laxative abuse in association with eating disorders or munchausen syndrome by proxy can cause unpredictable diarrhea. A high concentration of magnesium in the stool may indicate overuse of milk of magnesia or other magnesium-containing laxatives. Detection of other laxative preparations in the stool or circulation requires sophisticated analysis not available in most laboratories. A high index of suspicion and careful observation may be required to make this diagnosis.

E. Allergic Diarrhea

Diarrhea resulting from allergy to dietary proteins is a frequently entertained but rarely proven diagnosis. GI symptoms from cow’s milk protein allergy are more common in infants younger than 12 months.

In contrast to the self-limited cow’s milk protein hypersensitivity of infancy, infants and older children may develop more severe diarrhea caused by a systemic allergic reaction. For instance, food protein–induced enterocolitis syndrome (FPIES) is a life-threatening condition occurring during infancy manifested by large-volume diarrhea, acidosis, and shock as a result of an allergic reaction to common food proteins such as milk and soy. Patients require hospitalization for volume resuscitation and strict avoidance of allergens. Reintroduction of allergens should be performed in a controlled setting by an experienced allergist.

Infants and children may develop an enteropathy secondary to milk protein, resulting in flattening of small bowel villi, steatorrhea, hypoproteinemia, occult blood loss, and chronic diarrhea. Skin testing is not reliable since it detects circulating antibodies, not the T-cell–mediated responses that are likely responsible for food sensitivity reactions. Double-blind oral challenge with the suspected food under careful observation is often necessary to confirm this intestinal protein allergy. Small bowel biopsy findings are nonspecific. The diagnosis is often confirmed by either double-blind oral challenge with the suspected food or dietary elimination of the food followed by disappearance of occult blood in the stool and improvement in other symptoms. Consultation with an allergist is recommended for long-term management of patients with this disease.

Anaphylactic, immunoglobulin E (IgE)–mediated reactions to foods can occur in both young and older children. After ingestion, the patient quickly develops vomiting, then diarrhea, pallor, and hypotension. In these cases, radioallergosorbent test (RAST) and skin testing are positive. Food challenges should be undertaken in a setting in which resuscitation can be performed as there is often a progressively more severe reaction with subsequent ingestions. The close association between ingestion and symptoms usually leaves little doubt about the diagnosis.

F. Chronic Nonspecific Diarrhea

Chronic nonspecific diarrhea, also called toddler’s diarrhea, is the most common cause of loose stools in otherwise thriving children. The typical patient is a healthy, thriving child aged 6–20 months who has three to six loose stools per day during the waking hours. They do not have blood in their stools. They grow normally and may have a family history of functional bowel disease. No organic etiology is found for their diarrhea, with stool tests for blood, white blood cells, fat, parasites, and bacterial pathogens being negative. Diarrhea may worsen with a low-residue, low-fat, or high-carbohydrate diet and during periods of stress and infection. Excessive fruit juice ingestion seems to worsen symptoms. This syndrome resolves spontaneously usually by age 3½ years or after potty training. Possible causes of this diarrhea include abnormalities of bile acid absorption in the terminal ileum, excess intake of osmotically active carbohydrates, and abnormal motor function. A change in dietary fiber (either increasing fiber if deficient or decreasing fiber if excessive), a slight increase in dietary fat, and restriction of osmotically active carbohydrates like fruit juices will often help control symptoms. If these measures fail, loperamide (0.1–0.2 mg/kg/day in two or three divided doses) can be used as needed for symptomatic relief. Cholestyramine has also been used in some cases.

G. Immunologic Causes of Chronic Diarrhea

Chronic diarrhea is common in immune deficiency states, especially immunoglobulin A (IgA) deficiency and T-cell abnormalities. It can be due to an autoimmune enteropathy associated with the immune deficient state or could be due to chronic infection. The infectious causes of the diarrhea include common bacterial, viral, fungal, or parasitic organisms usually considered nonpathogenic (rotavirus, Blastocystis hominis, Candida), or unusual organisms (cytomegalovirus, Cryptosporidium, Isospora belli, Mycobacterium spp., microsporidia).

Between 50% and 60% of patients with common variable immune deficiency have enteropathy characterized by intestinal villous atrophy. Lymphonodular hyperplasia of the small intestine is also prominent. Patients with congenital or Bruton-type agammaglobulinemia usually have
diarrhea and abnormal intestinal morphology. Patients with isolated IgA deficiency can have chronic diarrhea, a celiac disease–like picture, lymphoid nodular hyperplasia, and are prone to giardiasis. Patients with isolated defects of cellular immunity, combined cellular and humoral immune incompetence, and HIV infection may have severe chronic diarrhea leading to malnutrition but often the cause cannot be identified. Chronic granulomatous disease may be associated with intestinal symptoms suggestive of chronic IBD. Specific treatments are available for many of the unusual pathogens causing diarrhea in the immunocompromised host. Thus, a vigorous diagnostic search for specific pathogens is warranted in these individuals. In addition, treatment must be directed toward correcting the immunologic defect.

H. Other Causes of Chronic Diarrhea

Most infections of the GI tract are acute and resolve spontaneously or with specific antibiotic therapy. Organisms most prone to cause chronic or recurrent diarrhea in immunocompetent children are *Giardia lamblia*, *Entamoeba histolytica*, *Salmonella* species, and *Yersinia*. Infection with these organisms requires a small inoculum. Some patients may develop a postinfectious diarrhea, with persistent diarrhea present despite the eradication of the offending organism, either viral or bacterial. Bacterial overgrowth of the small bowel in patients with SBS, those undergoing chemotherapy, or with anatomic abnormalities may experience chronic diarrhea.

Pancreatic insufficiency due to cystic fibrosis or Shwachman-Diamond syndrome may result in chronic diarrhea, typically in conjunction with failure to thrive. Certain tumors of childhood (neuroblastoma, ganglioneuroma, metastatic carcinoid, pancreatic VIPoma, or gastrinoma) may secrete substances such as gastrin and vasoactive intestinal polypeptide (VIP) that promote small intestinal secretion of water and electrolytes. Conditions that result in increased or disordered intestinal motility such as hyperthyroidism or irritable bowel syndrome may also present with diarrhea. Children may present with large-volume, chronic, and intermittent watery diarrhea that does not cease when they discontinue oral feedings.

Rebleeding is relatively common, with multicenter review of almost 10,000 pediatric GIB cases showing a 16% rate of emergency department evaluation and a 9% readmission rate within 30 days of the initial bleed. At the first evaluation, however, the history, physical examination, and initial evaluation are key to identifying the bleeding source. In large-volume, acute GI bleeding the primary focus, however, should center on stabilizing the patient to ensure adequate hemodynamic support.

### History

A number of substances simulate hematochezia or melena (Table 21–5). The presence of blood should be confirmed chemically with guaiac testing. Coughing, tonsillitis, lost teeth, menarche, or epistaxis may cause what appears to be occult or overt GI bleeding. A careful history of the specifics surrounding the bleeding is critical, including the site, volume and color or blood, history of NSAID use, and use of other medications should be ascertained. Inquiry about associated dysphagia, epigastric pain, or retrosternal pain should be made and, if present, suggest GER or a peptic cause of bleeding. Table 21–6 gives further cues in the presentation to help identify the source of bleeding.

Other important aspects of the history include foreign-body/caustic ingestion, history of chronic illnesses (especially liver/biliary disease), personal or family history of food allergy/atopy, associated symptoms (pain, vomiting, diarrhea, fever, weight loss), and family history of GI disorders

**Physical Examination**

The first objective of the examination is to determine if the child is acutely or chronically ill and initiate supportive measures as needed. Physical signs of portal hypertension, intestinal obstruction, or coagulopathy are particularly important. The nasal passages should be inspected for signs of recent epistaxis, the vagina for menstrual blood, and the...
anus for fissures and hemorrhoids. Skin examination should assess for hemangiomas, eczema, petechiae, or purpura.

A systolic blood pressure below 100 mm Hg and a pulse rate above 100 beats/min in an older child suggest at least a 20% reduction of blood volume. A pulse rate increase of 20 beats/min or a drop in systolic blood pressure greater than 10 mm Hg when the patient sits up is also a sensitive index of volume depletion. Tachycardia may be the initial indication of persistent bleeding.

**Laboratory Findings**

Initial laboratory tests should include a complete blood cell count (CBC), prothrombin time (PT), and partial thromboplastin time (PTT), at minimum. In specific cases it may be prudent to add a liver profile (with suspected variceal bleeding), erythrocyte sedimentation rate (ESR)/CRP (with possible IBD), BUN/creatinine (for possible hemolytic uremic syndrome). A BUN to creatinine ratio of more than 30 is generally less sensitive, requiring 1–2 mL/min. Angiography is generally less sensitive, requiring 1–2 mL/min.

**Imaging Studies**

In infants with acute onset of bloody stools, multiple-view plain x-rays of the abdomen are helpful in assessing for pneumatoasis intestinalis or signs of obstruction. Children younger than 2 with a history and examination suggestive of intussusception should undergo air or water-soluble contrast enema. Painless, large-volume bleeding may prompt performance of a $^{99m}$Tc-pertechnetate nuclear scan to assess for a Meckel diverticulum. Pretreatment with an H$_2$-receptor antagonist may be helpful in increasing the sensitivity of this study; however, a negative scan does not preclude the diagnosis. Performance of a Meckel scan at the time of initial presentation for bleeding has been shown to be associated with lower readmission rates in pediatric GI bleeding. CT scan of the abdomen with oral and IV contrast may be indicated to look for structural and inflammatory causes of bleeding. More recently, CT enterography has been proposed as a useful tool in cases of lower GI bleeding in children. Persistent bleeding without a clear source may prompt consideration of a radioisotope-tagged red blood cell (RBC) scan with $^{99m}$Tc-sulfur colloid, though the bleeding must be active at the time of the study, with a rate of at least 0.1 mL/min. Angiography is generally less sensitive, requiring 1–2 mL/min.

**Treatment**

In severe bleeding, the ABCs of resuscitation should be performed. Adequate IV access is critical in these cases. If a hemorrhagic diathesis is detected, vitamin K and additional blood products should be administered to correct any underlying coagulopathy. In severe bleeding, the need for volume replacement is monitored by measurement of central venous pressure. In less severe cases, vital signs, serial hematocrits, and gastric aspirates are sufficient.

In suspected upper GI bleeding, gastric lavage with saline should be performed, but there is no value of lavage in controlling bleeding. After stabilization, EGD may be considered to identify the bleeding site, and performance of endoscopy has been associated with lower readmission rates after an initial GI bleeding event. Endoscopy is superior to barium contrast study for lesions such as esophageal varices, stress ulcers, and gastritis. A large retrospective study of endoscopy performed for upper GI bleeding in children found that a definitive source for bleeding was identified in 57%, with a suspected source in another 30%. Risk factors for a nondiagnostic endoscopy in this series were a history of bleeding of less than 1 month and a delay of greater than
48 hours between presentation and endoscopy. Acid suppression with intravenous H₂-antagonists or, preferably PPIs, may be helpful in suspected peptic causes of bleeding. Colonoscopy may identify the source of bright red rectal bleeding, but it should be performed emergently only if the bleeding is severe and if abdominal radiographs show no signs of obstruction. Colonoscopy on an unprepared colon is often inadequate for making a diagnosis. Capsule endoscopy may be helpful to perform therapeutic interventions, obtain biopsies, or mark small bowel lesions (prior to laparotomy/laparoscopy) identified on capsule endoscopy. Use of balloon enteroscopy in conjunction with capsule endoscopy in children with occult GI bleeding has been found to have a diagnostic yield of 95%.

Persistent vascular bleeding (varices [Figure 21–7], vascular anomalies) may be relieved temporarily using intravenous octreotide (1–4 mcg/kg/h) and may be used for up to 48 hours with careful monitoring of glucose homeostasis. A single-center review of cases of massive variceal bleeding in children found a significant decrease in transfusion requirements with the use of octreotide. Bleeding from esophageal varices may be stopped by compression with a Sengstaken-Blakemore tube. Endoscopic sclerosis or banding of bleeding varices are both effective, with equivalent success rates (87%–89%) and complication rates (10%–19%) between methods. Endoscopic band ligation has been shown to be more effective and better tolerated than β-blockers as primary prophylaxis for variceal bleeding in pediatric cirrhotic patients in a recent single-center trial. Use of cyanoacrylate for gastric varices in children has been shown to be safe and effective in small, single-center studies.

If gastric decompression, acid suppressive therapy, and transfusion are ineffective in stopping ulcer bleeding, endoscopic therapy with argon plasma coagulation, local injection of epinephrine, electrocautery, or application of hemostatic clips may be employed. As in adults, use of only one modality in nonvariceal bleeding has been shown to increase the risk of rebleeding. If bleeding remains refractory to therapy, emergency surgery may be necessary. A single dose of cyclophosphamide has been shown to be effective in steroid-resistant GIB in Henoch Schonlein Purpura. In some cases, angiography and selective embolization have been used successfully in unidentified and refractory bleeding.

**VOMITING**

Vomiting is an extremely complex activity and is triggered by stimulation of chemoreceptors and mechanoreceptors in the wall of the GI tract, activated by contraction, distension, and physical damage. The vomiting center, paraventricular nuclei, in the brain controls the emetic response. These nuclei receive afferent input from many sources, abdominal splanchnic nerves, the vagus nerve, vestibulolabyrinthine receptors, the cerebral cortex, and chemoreceptor trigger
zone (CTZ). Vagal afferents from the gut to brain are stimulated by ingested drugs and toxins, mechanical stretch, inflammation, and local neurotransmitters. Additionally, local feedback loops in the gut also appear capable of initiating vomiting. Once the vomiting response is triggered, a pattern of somatic muscle action occurs with abdominal, thoracic, and diaphragm muscles contracting against a closed glottis. The resulting increased intra-abdominal pressure reverses the negative pressure of the esophagus and forces gastric contents upward. The vomiting response also alters intestinal motility by generating a retroperistaltic contractile complex that moves intestinal contents toward the esophagus.

Vomiting is the presenting sign of many pediatric conditions. The most common cause of vomiting in childhood is probably acute viral gastroenteritis. However, obstruction and acute or chronic inflammation of the GI tract and associated structures are also major causes. CNS inflammation, pressure, or tumor may cause vomiting. Metabolic derangements associated with inborn errors of metabolism, sepsis, and drug intoxication can stimulate either the CTZ or the brain directly to promote vomiting. Regurgitation associated with GE reflux of infants should be distinguished from vomiting. Occasionally, regurgitated fluid stimulates the pharyngeal afferents and provokes gagging or even a complete vomiting complex.

Control of vomiting with medication is rarely necessary in acute gastroenteritis, but it may relieve nausea and vomiting and decrease the need for intravenous fluids and/or hospitalization. Antihistamines and anticholinergics are appropriate for motion sickness because of their labyrinthine effects. 5-HT₃-receptor antagonists (ondansetron, granisetron) are useful for vomiting associated with surgery and chemotherapy. Benzodiazepines, corticosteroids, and substituted benzamides are also used in chemotherapy-induced vomiting. Butyrophenones (droperidol, haloperidol) are powerful drugs that block the D₂ receptor in the CTZ and are used for intractable vomiting in acute gastritis, chemotherapy, and after surgery. Phenothiazines are helpful in chemotherapy, cyclic vomiting, and acute GI infection but are not recommended for outpatient use because of extrapyramidal side effects.

1. Cyclic Vomiting Syndrome
   ▶ Clinical Findings

Cyclic vomiting syndrome (CVS) is defined as three or more recurrent episodes of stereotypical vomiting in children usually older than 1 year. The emesis is forceful and frequent, occurring up to six times per hour for up to 72 hours or more. Episode frequency ranges from two to three per month to less than one per year. Nausea, retching, and small-volume bilious emesis continue even after the stomach is emptied. Hematemesis secondary to forceful vomiting and a Mallory-Weiss tear may occur. Patients experience abdominal pain, anorexia, and, occasionally, diarrhea. Autonomic symptoms, such as pallor, sweating, temperature instability, and lethargy, are common and give the patient a very ill appearance. The episodes end suddenly, often after a period of sleep. In some children, dehydration, electrolyte imbalance, and shock may occur. Between episodes, the child is completely healthy.

The cause of CVS is unknown; however, a relationship to migraine headaches has long been recognized. Family history is positive for migraine in 50%–70% of cases and many patients develop migraine headaches as adults. Research suggests that abnormalities of neurotransmitters and hormones provoke CVS. About one-quarter of patients have typical migraine symptoms during episodes: premonitory sensation, headache, photophobia, and phonophobia. Identifiable triggers are similar to migraines and include infection, positive or negative emotional stress, diet (chocolate, cheese, monosodium glutamate), menses, sleep deprivation, or motion sickness.

▶ Differential Diagnosis

Conditions that mimic CVS include drug toxicity, increased intracranial pressure, seizures, brain tumor, Chiari malformation, recurrent sinusitis, choledochal cyst, gallstones, recurrent small bowel obstruction, IBD, familial pancreatitis, obstructive uropathy, recurrent urinary infection, diabetes, mitochondrial diseases, disorders of fatty and organic acid metabolism, adrenal insufficiency, and Munchausen syndrome by proxy. Although tests for reflux are often positive in these patients, it is unlikely that reflux and CVS are related.

▶ Treatment

Avoidance of triggers prevents episodes in some patients. Sleep can also end an episode although some children awaken and resume vomiting. Diphenhydramine or lorazepam is used at the onset of spells in some children to reduce nausea and induce sleep. Early use of antimigraine medications (sumatriptan), antiemetics (ondansetron), or antihistamines can abort spells in some patients. Once a spell is well established, intravenous fluids may be required to end it. With careful supervision, some children with predictable spells can receive intravenous fluids at home. Several approaches usually are tried before an effective therapy is found. Preventing spells with prophylactic propranolol, amitriptyline, antihistamines or anticonvulsants are effective.

in some patients with frequent or disabling spells. Some patients require the additions of the mitochondrial-targeted cofactors coenzyme Q10 and L-carnitine to help manage their vomiting episodes.

ABDOMINAL PAIN

Approximately 2%–4% of all pediatric office visits occur because of unexplained, recurrent abdominal pain. In addition, up to 17% of adolescents have been reported to have recurrent abdominal pain. Based on the Rome III criteria, the descriptive term “recurrent abdominal pain” has been discarded for the more meaningful terms that fall into the categories of “abdominal pain-related functional GI disorders” for children, which encompasses four entities: functional dyspepsia (characterized by epigastric pain), irritable bowel syndrome (characterized by altered form and frequency of stools and improvement with defecation), abdominal migraines, and childhood functional abdominal pain.

Clinical Findings

A. Symptoms and Signs

Children with functional abdominal pain experience recurrent attacks of abdominal pain or discomfort at least once per week for at least 2 months. Functional abdominal pain used to be lumped into a broad category of abdominal pain without a source and without any red flag signs. With the Rome III criteria, the classification of the abdominal pain depends on the characteristics of the pain such as location of pain, association with bowel habits and associated symptoms. The pain is usually localized to the periumbilical area but may also be more generalized. The pain occurs primarily during the day but may prevent children from falling asleep at night. It may be associated with pallor, nausea, or vomiting; and also with dramatic reactions such as frantic crying, clutching the abdomen, and doubling over. Parents may become alarmed and take their children into the emergency departments, where the evaluation is negative for an acute abdomen. School attendance may suffer, and enjoyable family events may be disrupted.

Alarm symptoms that would suggest a more severe organic etiology are absent. These include dysphagia, persistent vomiting, GI blood loss, associated rashes, or joint complaints. In addition, these children do not have a history of unintentional weight loss or fevers.

Functional abdominal pain usually bears little relationship to bowel habits and physical activity. However, some patients have a symptom constellation suggestive of irritable bowel syndrome, including bloating, postprandial pain, lower abdominal discomfort, and erratic stool habits with a sensation of obstipation or incomplete evacuation of stool. A precipitating or stressful situation in the child’s life at the time the pains began can sometimes be elicited. School phobia may be a precipitant. A history of functional GI complaints is often found in family members. A family history, however, of IBD, peptic ulcer disease, and CD is absent.

A thorough physical examination that includes a rectal examination is essential and usually normal. Complaints of abdominal tenderness elicited during palpation may be out of proportion to visible signs of distress.

B. Laboratory Findings

CBC, ESR, and stool test for occult blood are usually a sufficient evaluation. Extraintestinal sources such as kidney, spleen, and genitourinary tract may require assessment. In the adolescent female patient, ultrasound of the abdomen and pelvis may be helpful to detect gallbladder or ovarian pathology. If the pain is atypical, further testing suggested by symptoms and family history should be done. This may include additional imaging studies or endoscopic analysis.

Differential Diagnosis

Abdominal pain secondary to disorders causing acute abdomen are listed in Table 21–7. Pinworms, mesenteric lymphadenitis, and chronic appendicitis are improbable causes of recurrent abdominal pain. H pylori infection does not cause recurrent abdominal pain. Lactose intolerance usually causes abdominal distention, gas, and diarrhea with milk ingestion. At times, however, abdominal discomfort may be the only symptom. The incidence of peptic gastritis, esophagitis, duodenitis, and ulcer disease is probably underappreciated. Abdominal migraine and cyclic vomiting are conditions with an episodic character often associated with headaches or vomiting. Rarely, abdominal pain can be part of a broader symptom complex characterized by orthostatic intolerance and dysautonomia. The GI manifestations of dysautonomia may also include slow transit constipation, chronic nausea and recurrent vomiting along with other features related to a dysfunctional autonomic nervous system.

Treatment & Prognosis

Treatment consists of reassurance based on a thorough history and physical examination and a sympathetic, age-appropriate explanation of the nature of functional pain. It is important to acknowledge that the child is experiencing pain.
The concept of “visceral hyperalgesia” or increased pain signaling from physiologic stimuli such as gas, acid secretion, or stool is one that parents can understand and helps them respond appropriately to the child’s complaints. Another analogy might be to compare a child’s abdominal pain to usual headaches that another person may experience, in that the workup can be normal even though there is pain. Reassurance without education is rarely helpful. Regular activity should be resumed, especially school attendance. Therapy for psychosocial stressors, including biofeedback therapy, may be necessary. In older patients, and in those with what appears to be visceral hyperalgesia, amitriptyline in low doses may occasionally be helpful. Antispasmodic medications are rarely helpful and should be reserved for patients with more typical irritable bowel complaints. For IBS, targeted therapy based on symptoms may be helpful. For abdominal migraines, treatments for migraine headaches may also help.

ACUTE ABDOMEN

An acute abdomen is a constellation of findings indicating an intra-abdominal process that may require surgery. A degree of urgency is implied when this diagnosis is suspected. The pain of an acute abdomen intensifies over time and is rarely relieved without definitive treatment. Pain is often accompanied by nausea, vomiting, diarrhea, fever, and anorexia. Pain may be localized or generalized. The abdomen may be distended and tense, and bowel sounds reduced or absent. Patients appear ill and are reluctant to be examined or moved. The acute abdomen is usually a result of infection of the intra-abdominal or pelvic organs, but it also occurs with intestinal obstruction, intestinal perforation, inflammatory conditions, trauma, and some metabolic disorders. Some of the conditions causing acute abdomen are listed in Table 21-8. Reaching a timely and accurate diagnosis is critical and requires skill in physical diagnosis, recognition of the symptoms of a large number of conditions, and a judicious selection of laboratory and radiologic tests. (Acute appendicitis is discussed earlier in the section Disorders of the Small Intestine.)

MALABSORPTION SYNDROMES

Malabsorption of ingested food has many causes (see Table 21-8). Shortened length (usually via surgical resection) and mucosal damage (CD) both reduce surface area. Impaired motility interferes with normal propulsive movements and with mixing of food with pancreatic and biliary secretions and permits anaerobic bacterial overgrowth. Bacterial overgrowth may lead to increased carbohydrate fermentation and acidic diarrhea. Bacterial overgrowth may also increase bacterial bile acid deconjugation leading to fat malabsorption as seen in intestinal pseudo-obstruction or postoperative blind loop syndrome. Impaired intestinal lymphatic (congenital lymphangiectasia) or venous drainage also causes malabsorption. Diseases reducing pancreatic exocrine function (cystic fibrosis, Shwachman syndrome) or the production and flow of biliary secretions cause nutrient malabsorption. Malabsorption of specific nutrients may also be genetically determined (acrodermatitis enteropathica, disaccharidase deficiency, glucose-galactose malabsorption, and abetalipoproteinemia).

Clinical Findings

Diarrhea, vomiting, anorexia, abdominal pain, failure to thrive, and abdominal distention are common. With fat malabsorption, stools are typically bulky, foul, greasy, and pale; in contrast, osmotic diarrhea stools are loose, watery, and acidic. Stool microscopic examination for neutral fat (pancreatic insufficiency as in cystic fibrosis)
and fatty acids (as in mucosal injury, liver disease) may be useful.

Quantifying fat malabsorption by timed stool collection compares amount of ingested to excreted fat. Stool loss of 10%–15% of ingested fat is normal in infancy, while loss of 5% of ingested fat is normal for 1- to 10-year-olds. Fat-soluble vitamin deficiency occurs with long-standing fat malabsorption and is manifested by prolonged PT (vitamin K) and low levels of serum carotene (vitamin A), vitamin E, and 25-hydroxy vitamin D. Loss of serum proteins across the intestinal mucosa is suggested by elevated fecal α₁-antitrypsin levels. Disaccharide or monosaccharide malabsorption manifests by acidic stool with pH less than 5.5 due to lactic acid and reducing substances. Specific enzyme deficiencies may be evaluated by breath hydrogen test, or specific disaccharidase activity measurement from small intestinal biopsy, in the presence of normal histology. Other screening tests suggesting a specific diagnosis include sweat chloride concentration (cystic fibrosis), intestinal mucosal biopsy (CD, lymphangiectasia, IBD), liver and gallbladder function tests, and fecal elastase. Some of the most common disorders associated with malabsorption in pediatric patients are detailed as follows.

1. Protein-Losing Enteropathy

Loss of plasma proteins into the GI tract occurs in association with intestinal inflammation, intestinal graft-versus-host disease, acute and chronic intestinal infections, venous and lymphatic obstruction or malformations, and intestinal malignancy. Chronic elevation of venous pressure in children with the Fontan procedure and elevated right-sided heart pressures may produce protein-losing enteropathy.

**Clinical Findings**

Signs and symptoms are mainly caused by hypoproteinemia or fat malabsorption: edema, ascites, poor weight gain, anemia, and specific vitamin (fat-soluble vitamins A, D, E, K) and mineral deficiencies. Serum albumin and globulins may be decreased. Fecal α₁-antitrypsin is elevated (> 3 mg/g dry weight stool; slightly higher in breast-fed infants). Disorders associated with protein-losing enteropathy are listed in Table 21–9. In the presence of intestinal bleeding, fecal α₁-antitrypsin measurements are falsely high.

**Differential Diagnosis**

Hypoalbuminemia may be due to increased catabolism, poor protein intake, impaired hepatic protein synthesis, or congenital malformations of lymphatics outside the GI tract, and protein losses in the urine from nephritis and nephrotic syndrome.

**Table 21–9. Disorders associated with protein-losing enteropathy.**

**Treatment**

Albumin infusion, diuretics, and a high-protein, low-fat diet may control symptoms. Nutritional deficiencies should be addressed, and additional treatment is based on identifying the underlying cause.

2. Celiac Disease (Gluten Enteropathy)

*Celiac disease* (CD) is an immune-mediated enteropathy triggered by gluten, a protein in wheat, rye, and barley. CD presents any time after gluten is introduced in the diet, with symptoms of abdominal pain, diarrhea, vomiting, distention, and sometimes constipation. Other manifestations include oral ulcers, a pruritic rash (dermatitis herpetiformis), growth and pubertal delay, iron deficiency anemia, decreased bone mineralization, and arthritis. Disease frequency in Western populations approaches 1 in 100. Risk factors include type 1 diabetes (4%–10%), Down syndrome (5%–12%), Turner syndrome (4%–8%), IgA deficiency (2%–8%), autoimmune
thyroiditis (8%), and family history of CD (5%–10%). Almost all CD patients express HLA-DQ2 or DQ8 tissue antigens.

**Clinical Findings**

**A. Symptoms and Signs**

1. **Gastrointestinal manifestations**—In the classic form of CD, GI symptoms begin soon after gluten-containing foods are introduced in the diet, usually between 6 and 24 months of age. Chronic diarrhea, abdominal distention, irritability, anorexia, vomiting, and poor weight gain are typical. Celiac crisis, with dehydration, hypotension, hypokalemia, and explosive diarrhea, is rare. Older children may have chronic abdominal pain, vomiting, diarrhea or constipation, and bloating that mimic lactose intolerance, functional abdominal pain, or irritable bowel syndrome.

2. **Nongastrointestinal manifestations**—Adolescents may present with delayed puberty or short stature, and in females, delayed menarche. CD should be considered in children with unexplained iron-deficiency anemia, decreased bone mineral density, elevated liver function enzymes, arthritis, or epilepsy with cerebral calcifications, or rash suggestive of dermatitis herpetiformis. The benefit of early screening and treatment in asymptomatic individuals is unclear.

**B. Laboratory Findings**

1. **Serologic and genetic testing**—Highly sensitive and specific screening tests in IgA-sufficient patients are the IgA antitissue transglutaminase or IgA antiendomysial antibody tests. In IgA deficiency, IgG-based versions of these assays are available. Testing for HLA-DQ2 and DQ8 has a high negative predictive value. Family members who test negative are unlikely to ever develop CD.

2. **Stools**—Stools may have partially digested fat and may be acidic.

3. **Hypoalbuminemia**—Hypoalbuminemia can be severe enough to lead to edema.

4. **Anemia**—Anemia with low MCV and evidence of iron deficiency is common.

**C. Biopsy Findings**

Characteristic duodenal biopsy findings on light microscopy are villous atrophy with increased numbers of intraepithelial lymphocytes. Findings may be patchy.

**Differential Diagnosis**

The differential diagnosis includes food allergy, Crohn disease, postinfectious diarrhea, immunodeficiencies, graft-versus-host disease, and hypergastrinemia (Zollinger-Ellison syndrome).

**Treatment**

**A. Diet**

Treatment is dietary gluten restriction for life. All sources of wheat, rye, and barley are eliminated. Most, but not all, patients tolerate oats. The intestinal mucosa improves by 6–12 months while lactose intolerance resolves often within a few weeks. Suplemental calories, vitamins, and minerals are indicated only in the acute phase. CD-related antibody titers decrease on a gluten-free diet.

**B. Corticosteroids**

Corticosteroids are indicated for celiac crisis with profound anorexia, edema, abdominal distention, and hypokalemia.

**Prognosis**

Adherence to gluten-free diet is associated with normal life. Individuals with poor adherence to gluten-free diet may be at increased risk for fractures, iron deficiency anemia, infertility, and enteropathy-associated T-cell lymphoma.

**3. Carbohydrate Malabsorption**

Carbohydrate malabsorption is typically a nonimmune-mediated intolerance to dietary carbohydrates due to a deficiency in an enzyme or transporter, or due to excess consumption overloading a functional transporter. These systems are located on the small bowel epithelial brush border. The nonabsorbed molecules cause osmotic diarrhea and are fermented in the gut producing gas. As a result, clinical symptoms include abdominal distention, bloating, flatulence, abdominal discomfort, nausea, and typically watery diarrhea. Stools will test positive for reducing substances, except for sucrose, which is not a reducing sugar.

**A. Disaccharidase Deficiency**

Starches and the disaccharides sucrose and lactose are the most important dietary carbohydrates. Dietary disaccharides and the oligosaccharide products of pancreatic amylase
action on starch require hydrolysis by intestinal brush border disaccharidases for absorption. Disaccharidase levels are highest in the jejunum and proximal ileum. Characteristics of primary disaccharidase deficiency include permanent disaccharide intolerance, absence of intestinal injury, and frequent positive family history. Transient secondary disaccharidase deficiency may be caused by mucosal damage, such as from acute viral enteritis.

B. Lactase Deficiency
Congenital lactase deficiency is extremely rare. All human ethnic groups are lactase-sufficient at birth. Genetic or familial lactase deficiency appears after 5 years of age. Genetic lactase deficiency develops in virtually all Asians, Alaskan natives, and Native Americans, 80% of Africans, 70% of African Americans, and 30%–60% of Caucasian Americans. Transient or secondary lactase deficiency caused by mucosal injury such as an acute viral gastroenteritis is common and resolves within a few weeks.

Lactase ingestion in lactase deficient individuals causes variable degrees of diarrhea, abdominal distention, flatus, and abdominal pain. Stools are liquid or frothy and acidic, and may test positive for reducing substances. Diagnostic tests include genetic testing and lactose breath test. Symptoms resolve with dietary avoidance of lactose or with lactase supplementation.

C. Sucrase-Isomaltase Deficiency
This condition is inherited in an autosomal recessive fashion and is most common in Greenland, Iceland, and among Alaskan natives. The condition is rare in other groups. Infants may present with abdominal distention, failure to thrive, and watery, acidic diarrhea. Diagnosis is made by oral sucrose breath hydrogen testing (1 g/kg), or by testing a snap frozen intestinal biopsy for enzyme activity. Partial enzyme deficiencies exist. Treatment is avoidance of sucrose and starches rich in amylopectin, or the use of sacrosidase enzyme supplement.

CSID parent support group: www.csidinfo.com.
QOL Medical, LLC: www.sucraid.net.

4. Monosaccharide Malabsorption
The most important monosaccharides are fructose, glucose, and galactose.

A. Glucose-Galactose Malabsorption
Glucose-galactose malabsorption is a rare disorder in which the sodium-glucose transport protein is defective. Transport of glucose in the intestinal epithelium and renal tubule is impaired. Diarrhea begins with the first feedings, accompanied by reducing sugar in the stool and acidosis. Small bowel histology is normal. Glycosuria and aminoaciduria may occur. The glucose tolerance test is abnormal. Fructose is well tolerated. Diarrhea subsides promptly on withdrawal of glucose and galactose from the diet. The acquired, transient form of glucose-galactose malabsorption occurs mainly in infants younger than 6 months, usually following acute viral or bacterial enteritis, and may require PN until healing.

In the congenital disease, exclusion of glucose and galactose from the diet is mandatory. A carbohydrate-free base formula is used with added fructose. Prognosis is good if diagnosed early. Tolerance for glucose and galactose improves with age.

B. Dietary Fructose Intolerance
Fructose malabsorption occurs when fructose is in excess of glucose, often with consumption of high-fructose corn syrup. Malabsorbed fructose leads to symptoms such as abdominal pain, bloating, flatulence, and diarrhea. Diagnosis is made with a fructose breath hydrogen test.

C. Intestinal Lymphangiectasia
This form of protein-losing enteropathy results from a congenital ectasia of the intestinal lymphatics and is often associated with abnormalities of the lymphatics in the extremities. Obstruction of lymphatic drainage leads to leakage of lymph into the bowel lumen.

Clinical Findings
Peripheral edema, diarrhea, abdominal distention, chylous effusions, and repeated infections are common. Laboratory findings include low calcium, magnesium, albumin, immunoglobulin levels, lymphocytopenia, and anemia. Fecal α₁-antitrypsin is elevated. Imaging may show bowel wall edema, and biopsy may reveal dilated lacteals in the villi and lamina propria. If only the lymphatics of the deeper layers of bowel or intestinal mesenteries are involved, laparotomy may be necessary to establish the diagnosis. Capsule endoscopy shows diagnostic brightness secondary to the fat-filled lacteals.

Differential Diagnosis
Other causes of protein-losing enteropathy must be considered, although an associated lymphedematous extremity strongly favors this diagnosis.

Treatment & Prognosis
A high-protein diet (6–7 g/kg/day may be needed) enriched with medium-chain triglycerides as a fat source usually
allows for adequate nutrition and growth. The serum albumin may not normalize. Vitamin and calcium supplements should be given. Parenteral nutritional supplementation may be needed temporarily. Surgery may be curative if the lesion is localized to a small area of the bowel or in cases of constrictive pericarditis or obstructing tumors. IV albumin and immune globulin may be needed but usually not chronically. The prognosis is not favorable, although remission may occur with age. Malignant degeneration of the abnormal lymphatics may occur, and intestinal B-cell lymphoma may develop.

5. Cow’s Milk Protein Intolerance

Milk protein intolerance refers to nonallergic food sensitivity and is more common in males than females and in young infants with a family history of atopy. The estimated prevalence is 0.5%–1.0%. Symptoms may occur while an infant is still exclusively breast-fed. The most common form is a healthy infant with flecks of blood in the stool or with loose mucoid stools with streaks of blood. Exposure to cow’s milk protein is from formula or breast milk. A family history of atopy is common. Skin testing is not reliable and is not indicated. Treatment is eliminating the source of the protein; maternal avoidance of milk protein will usually suffice if breast-fed. If formula-fed, substituting a protein hydrolysate formula for cow’s milk–based formula is indicated. A more severe form of FPIES may require steroids. Allergic colitis in young infants is self-limited, usually disappearing by 8–12 months of age. Since no long-term consequences of this problem have been identified, when symptoms are mild and the infant is thriving, no treatment may be needed. Histology, not required for diagnosis, shows mild lympho- nodular hyperplasia, mucosal edema, and eosinophilia on rectal biopsy.

In older children, milk protein sensitivity may induce eosinophilic gastroenteritis with protein-losing enteropathy, iron deficiency, hypoalbuminemia, and hypogammaglobulinemia. A celiac-like syndrome with villous atrophy, malabsorption, hypoalbuminemia, occult blood in the stool, and anemia can occur.

6. Pancreatic Insufficiency

The most common cause of pancreatic exocrine insufficiency in childhood is cystic fibrosis. Decreased secretion of pancreatic digestive enzymes is caused by obstruction of the exocrine ducts by thick secretions, which destroys pancreatic acinar cells. Other conditions associated with exocrine pancreatic insufficiency are discussed in Chapter 22.

7. Other Genetic Disorders Causing Malabsorption

A. Abetalipoproteinemia

Abetalipoproteinemia is a rare autosomal recessive condition in which the secretion of triglyceride-rich lipoproteins from the small intestine (chylomicrons) and liver (very low-density lipoproteins) is abnormal. Profound steatosis of intestinal enterocytes (and hepatocytes) and severe fat malabsorption occur. Deficiencies of fat-soluble vitamins develop with neurologic complications of vitamin E deficiency and atypical retinitis pigmentosa. Serum cholesterol level is very low, and red cell membrane lipids are abnormal, causing anacanthosis of red blood cells, which may be the key to diagnosis.

B. Acrodermatitis Enteropathica

Acrodermatitis enteropathica is an autosomal recessive condition in which the intestine has a selective inability to absorb zinc. The condition usually becomes obvious at the time of weaning from breast-feeding and is characterized by rash on the extremities, rashes around the body orifices, eczema, profound failure to thrive, steatorrhea, diarrhea, and immune deficiency. Zinc supplementation by mouth results in rapid improvement.

INFLAMMATORY BOWEL DISEASE

» General Considerations

Inflammatory bowel disease (IBD), a chronic relapsing inflammatory disease, is most commonly differentiated into Crohn disease (CrD) and ulcerative colitis (UC). The etiology is multifactorial, involving a complex interaction of environmental and genetic factors leading to maladaptive immune responses to flora in the GI tract. With 5%–30% of patients identifying a family member with IBD, and a 10–20 relative risk of a sibling developing IBD, a genetic association is evident. Very early onset IBD, before age 2, is more likely to be monogenic and severe.

» Clinical Findings

A. Symptoms and Signs

Most commonly, inflammation causes abdominal pain, diarrhea, bloody stools, fever, anorexia, fatigue, and weight loss. CrD may also present as a strictureing process with abdominal pain and intestinal obstruction, or as a penetrating/fistulizing form with abscess, perianal disease, or symptoms similar to acute appendicitis. UC usually presents with abdominal pain and bloody diarrhea.

CrD can affect any part of the GI tract from lips to anus. Childhood CrD most often affects the terminal
ileum and colon. UC is limited to the colon, and in children it usually involves the entire colon (pancolitis). The younger the age at onset, the more severe the course is likely to be.

Extraintestinal manifestations are common in both forms of IBD and may precede the intestinal complaints. These include uveitis, recurrent oral aphthous ulcers, arthritis, growth and pubertal delay, liver involvement (typically primary sclerosing cholangitis), rash (erythema nodosa and pyoderma gangrenosum), and iron deficiency anemia.

B. Diagnostic Testing

Diagnosis is based on typical presentation, course, radiographic, endoscopic, and histologic findings, and exclusion of other disorders. No single test is diagnostic. Patients with IBD often have low hemoglobin, iron, and serum albumin levels, and elevated ESR and CRP and fecal calprotectin. IBD-related serum antibodies are frequently present; antibodies to *Saccharomyces cerevisiae* (ASCA) in 60% of CrD, and perinuclear antineutrophil cytoplasmic antibodies (pANCA) in 70% of UC. These, and other IBD-related antibodies, may be helpful in differentiating CrD from UC, but they are neither sensitive nor specific enough to be diagnostic. Abdominal imaging with CT, magnetic resonance enterography, US, and barium upper GI radiographs with small bowel follow-through may reveal small bowel disease and exclude other etiologies. Findings include terminal ileal thickening, enteric fistulas, and mucosal and mural edema.

Upper endoscopy and ileocolonoscopy are the most useful diagnostic modalities, revealing severity and extent of upper intestinal, ileal, and colonic involvement. MR enterography and capsule endoscopy image the entire small bowel. Granulomas are found in 25%–50% of CrD cases. Deep linear ulcers, white exudate (Figure 21–8), aphthous lesions (Figure 21–9), patchy involvement, and perianal disease suggest CrD. Superficial and continuous involvement of the colon sparing the upper GI tract are most consistent with UC. Both forms of IBD may have mild gastritis.

Differential Diagnosis

When extraintestinal symptoms predominate, CrD can be mistaken for rheumatoid arthritis, systemic lupus erythematosus or other vasculitis, CD, or hypopituitarism. The acute onset of ileocolitis may be mistaken for intestinal obstruction, appendicitis, lymphoma, infectious diarrhea. Malabsorption symptoms suggest CD, peptic ulcer, *Giardia*, food protein allergy, anorexia nervosa, or growth failure from endocrine causes. Perianal disease may suggest child abuse. Crampy diarrhea and blood in the stool can also occur with infection such as *Shigella*, *Salmonella*, *Yersinia*, *Campylobacter*, *E histolytica*, enteroinvasive *E coli* (*E coli* O157), *Aeromonas hydrophila*, *C difficile*, and, if immunocompromised, CMV. Mild IBD mimics irritable bowel syndrome, or lactose intolerance. Consider Behçet disease...
if there are deep intestinal ulcers, oral aphthous ulcerations along with at least two of the following: genital ulcers, synovitis, posterior uveitis, meningoencephalitis, and pustular vasculitis. Chronic granulomatous disease and sarcoidosis also cause granulomas.

Complications

A. Crohn Disease

Nutritional complications include failure to thrive, short stature, decreased bone mineralization, and specific nutrient deficiencies, including iron, calcium, zinc, vitamin B12, and vitamin D. Prolonged corticosteroid therapy may impact growth and bone mineral density. Most patients achieve reasonable final adult height. Intestinal obstruction, fistulae, abdominal abscess, perianal disease, pyoderma gangrenosum, arthritis, and amyloidosis occur. Crohn colitis increases risk for colon adenocarcinoma.

B. Ulcerative Colitis

Even with the typical features and course of UC, up to 3%–5% of patients will develop clear CrD. Arthritis, uveitis, pyoderma gangrenosum, and malnutrition all occur. Growth failure and delayed puberty are less common than in CrD while liver disease (chronic active hepatitis, sclerosing cholangitis) is more common. Adenocarcinoma of the colon occurs with an incidence of 1%–2% per year after the first 7–8 years of disease in patients with pancolitis and is significantly higher in patients with both UC and sclerosing cholangitis.

Treatment

A. Medical Treatment

Therapy for pediatric IBD involves induction of remission, maintenance of remission, and addressing nutritional deficiencies to promote normal growth and development. Treatment includes anti-inflammatory, immunomodulatory, anti-diarrheal, antibiotic, and biological options. No medical therapy is uniformly effective in all patients. In severe CrD, growth hormone may be needed to attain full height potential.

1. Diet—Enteral nutrition with liquid formula providing more than 85% of caloric needs is an effective therapy for both induction and maintenance of remission for CrD and it promotes linear growth. Diet therapies are less effective in UC. Ensuring adequate nutrition for replenishing deficits and promoting normal growth (including pubertal growth) can be challenging. In addition to total calories, micronutrient, calcium, and vitamin deficiencies should be replenished. Restrictive or bland diets are counterproductive because they usually result in poor intake. A high-protein, high-carbohydrate diet with normal amounts of fat is recommended. A diet with decreased fiber may reduce symptoms during active colitis or partial intestinal obstruction; however, once the colitis is controlled, increased fiber may benefit mucosal health via bacterial production of fatty acids. Low-lactose diet or lactase replacement may be needed temporarily for small bowel CrD. Ileal disease may require antibiotics to treat bacterial overgrowth and extra fat-soluble vitamins due to increased losses. Supplemental calories in the form of liquid diets or enteral (nasogastric [NG] tube supplements) are well tolerated and promote catch-up growth in severe CrD.

2. Aminosalicylates (ASA)—Multiple preparations of 5-ASA derivatives are available and used to induce and maintain remission in mild CrD and UC. Common preparations including 5-ASA products such as sulfasalazine (50 mg/kg/day), or balsalazide (0.75–2.5 g PO tid) or mesalamine products (adult dose range 2.4–4.8 g/day), are available in tablets, granules, and delayed release formulations targeting specific locations in the GI tract. Side effects include skin rash; nausea; headache and abdominal pain; hair loss; diarrhea; and rarely nephritis, pericarditis, serum sickness, hemolytic anemia, aplastic anemia, and pancreatitis. Sulfasalazine, in which sulfa delivers the 5-ASA, may cause sulfa-related side effects including photosensitivity and rash.

3. Corticosteroids—Patients with moderate to severe CrD and UC generally respond quickly to corticosteroids. Methylprednisolone (1 mg/kg/day) may be given intravenously when disease is severe. For moderate disease, prednisone (1 mg/kg/day, orally in one to two divided doses) is given until symptomatic response, followed by gradual tapering over 4–8 weeks. A flare is common during the taper, requiring re-induction and a slower taper course. Steroid dependence is an indication for escalating therapy. Ileocecal CrD is effectively treated with budesonide (9 mg QAM), with less side effects than systemic steroids, due to “single-pass” clearance by the liver. Corticosteroid enemas and foams are useful topical agents for distal proctitis or left-sided colitis. While on systemic corticosteroids, consideration should be given to calcium and vitamin D supplementation as well as acid suppression to prevent gastritis.

4. Immunomodulators: azathioprine (AZA), 6-mercaptopurine (6MP), and methotrexate (MTX)—If IBD is moderate to severe, or the patient is steroid-dependent, immunomodulators are effective in maintaining remission and reducing corticosteroid use. AZA (2–3 mg/kg/day PO) or 6MP (1–2 mg/kg/day PO) provides effective maintenance therapy for moderate to severe CrD. The optimal dose of AZA or 6MP depends on the enzyme thiopurine methyltransferase (TPMT), which should be assessed before starting therapy. For individuals deficient in TPMT, MTX should be used; for intermediate enzyme activity, dose
is reduced by 50%. In cases where adherence may be an
issue, or where dose adjustments may be necessary, AZA or
6MP metabolites may be measured. Maximum therapeutic
efficacy may not be seen for 2–3 months after beginning
treatment. Side effects include pancreatitis, hepatotoxicity,
and bone marrow suppression.

MTX has a more rapid onset of action, usually 2–3 weeks,
and is given in weekly doses, orally or intramuscularly, about
15 mg/m² weekly. Most common side effect is nausea, man-
aged with folate 1 mg a day the other 6 days a week, while
serious adverse events include bone marrow, liver, lung, and
kidney toxicities. MTX is well known to cause fetal death and
deformities.

5. Antibiotics—Metronidazole (15–30 mg/kg/day in three
divided doses) and ciprofloxacin treat perianal CrD and
bacterial overgrowth. Peripheral neuropathy may occur with
prolonged use of metronidazole.

6. Biologics—Antibody against tumor necrosis factor-α
(TNFα) is used for moderate to severe CrD and UC, and for
fistulizing or penetrating disease. Formulations are available
for IV (infliximab) or intramuscular (adalimumab) adminis-
tration. Recurrence of disease often occurs within 12 months
of stopping therapy. New biologicals include vedolizumab,
an alpha4/beta7 anti-integrin, and ustekinumab, an anti
IL12/23 agent. Use of biologics is associated with risk for
infusion reactions, injection site reactions, and increased
risk for opportunistic infections and for malignancy. Rarely,
hepatosplenic T-cell lymphoma is associated with anti-TNF
agents and concomitant AZA/6MP.

7. Other agents—Cyclosporine or tacrolimus may be used
as a “bridge” to more definitive therapy (such as colectomy
for UC). Probiotics and prebiotics are frequently used but
with very limited data on efficacy.

8. Surveillance—After 7–8 years of colitis, cancer screening
with routine colonoscopy and multiple biopsies is recom-
manded. Persistent metaplasia, aneuploidy, or dysplasia
indicates need for colectomy.

B. Surgical Treatment

1. Crohn disease—Ileocecal resection is the most com-
mon surgery but is not curative and recurrence is expected.
Indications for surgery in CrD include stricture, obstruction,
uncontrollable bleeding, perforation, abscess, fistula, and
failure of medical management. Up to 50% of patients with
CrD eventually require a surgical procedure.

2. Ulcerative colitis—Total colectomy is curative and is
recommended for patients with steroid dependence or ste-
roid resistance, uncontrolled hemorrhage, toxic megacolon,
high-grade dysplasia, or malignant tumors; elective colec-
tomy may be chosen for prevention of colorectal cancer after
7–8 years of disease. Colectomy requires a temporary ileo-
stomy. A J-pouch provides better continence, but pouchitis
develops in up to 25% of patients, manifested by diarrhea
and cramping, and is treated with metronidazole or cipro-
fl oxacin. Liver disease associated with IBD is not improved
by colectomy.

▶ Quality Improvement

The ImproveCareNow network develops collaborative, data-
driven improvements in the health of children with IBD. Remission rates have increased to greater than 75%.

by pigmented stools and lack of bile duct proliferation and portal tract bile plugs on liver biopsy. Bile duct patency can be confirmed least invasively by hepatobiliary scintigraphy using technetium-99m (99mTc)-dimethyliminodiacetic acid (diethyl-IDA [DIDA]). Radioactivity in the bowel within 4–24 hours is evidence of bile duct patency, as is finding bilirubin in duodenal aspirates. However, these tests are rarely needed in the clinical setting. Patency can also be determined, when clinically indicated, by cholangiography carried out either intraoperatively, percutaneously by transhepatic cholecystography, or by endoscopic retrograde cholangiopancreatography (ERCP) using a pediatric-size side-viewing endoscope. Magnetic resonance cholangiopancreatography in infants is of limited use and highly dependent on the operator and equipment.

1. Perinatal or Neonatal Hepatitis Resulting From Infection

This diagnosis is considered in infants with jaundice, hepatomegaly, vomiting, lethargy, fever, and petechiae. It is important to identify perinatally acquired viral, bacterial, or protozoal infections (Table 22–3) as they may be treatable. Infection may occur transplacentally, by ascent through the cervix into amniotic fluid, from swallowed contaminated fluids (maternal blood, urine, vaginal secretions) during delivery, from blood transfusions administered in the early neonatal period, or from breast milk or environmental exposure. Infectious agents include herpes simplex virus, varicella virus, enteroviruses (coxsackievirus and echovirus), cytomegalovirus (CMV), rubella virus, adenovirus, parvovirus, human herpesvirus type 6 (HHV-6), hepatitis B virus (HBV), human immunodeficiency virus (HIV), Treponema pallidum, and Toxoplasma gondii. Although hepatitis C may be transmitted vertically, it rarely causes neonatal cholestasis. The degree of liver cell injury caused by these agents is variable, ranging from massive hepatic

</tr>
<tr>
<td>Associated cause identified (infections, metabolic, familial, etc)</td>
<td>Polysplenia or asplenia syndromes, midline liver</td>
</tr>
</tbody>
</table>

Clinical Findings

Clinical symptoms typically present in the first 2 weeks of life, but may appear as late as age 2–3 months. Poor oral intake, poor sucking reflex, lethargy, hypotonia, and vomiting are frequent. Stools may be normal to pale in color, but are seldom acholic. Dark urine stains the diaper. Firm hepatomegaly is present and splenomegaly is variably present. Macular, papular, vesicular, or petechial rashes may occur. Unusual presentations include neonatal liver failure, hypoproteinemia, anasarca (nonhemolytic hydrops), and hemorrhagic disease of the newborn.

Differential Diagnosis

Great care must be taken to distinguish infectious causes of intrahepatic cholestasis from genetic or metabolic disorders because the clinical presentations are similar and may overlap. Galactosemia, hereditary fructose intolerance, and tyrosinemia must be investigated promptly, because specific therapy is available. These infants may also have concomitant bacteremia. α1-Antitrypsin deficiency, cystic fibrosis, bile acid synthesis defects, progressive familial intrahepatic cholestasis, mitochondrial respiratory chain disorders, and neonatal iron storage disease must also be considered. Specific physical features may suggest Alagille syndrome, arthrogryposis/renal dysfunction/cholestasis (ARC) syndrome or Zellweger syndrome. Idiopathic neonatal hepatitis (transient neonatal cholestasis) can be indistinguishable from infectious causes.
Infections with herpes simplex virus, varicella, CMV, parvovirus, and toxoplasmosis have specific treatments (see Table 22–3). Penicillin for suspected syphilis, specific antiviral therapy, or antibiotics for bacterial hepatitis need to be administered promptly. Intravenous dextrose is needed if feedings are not well tolerated. The consequences of cholestasis are treated as indicated (Table 22–4). Vitamin K orally or by injection and vitamins D and E orally should be provided. Choleretics (ursodeoxycholic acid [UDCA]) are used if cholestasis persists. Corticosteroids are contraindicated.

Ag, viral antigen testing; CSF, cerebrospinal fluid; HBcAg, hepatitis B core antigen; HBsAg, hepatitis B surface antigen; INH, isoniazid; IVIG, intravenous immune globulin; PCR, polymerase chain reaction test for viral DNA or RNA; PPD, purified protein derivative.

IgG = positive indicates maternal infection and transfer of antibody transplacentally; negative indicates unlikelihood of infection in mother and infant.

Use foscarnet for resistant viruses, which should be rare in the neonate. Treat only if symptomatic.

**Treatment**

Infections with herpes simplex virus, varicella, CMV, parvovirus, and toxoplasmosis have specific treatments (see Table 22–3). Penicillin for suspected syphilis, specific antiviral therapy, or antibiotics for bacterial hepatitis need to be administered promptly. Intravenous dextrose is needed if feedings are not well tolerated. The consequences of cholestasis are treated as indicated (Table 22–4). Vitamin K orally or by injection and vitamins D and E orally should be provided. Choleretics (ursodeoxycholic acid [UDCA]) are used if cholestasis persists. Corticosteroids are contraindicated.

**Prognosis**

Multiple organ involvement portends a poor outcome. Hepatic or cardiac failure, intractable acidosis, or intracranial hemorrhage are associated with fatal outcome in herpesvirus, adenovirus, or enterovirus infections, and occur occasionally in CMV or rubella infection. HBV rarely causes fulminant neonatal hepatitis; most infected infants are immunotolerant to hepatitis B. The neonatal liver usually recovers without fibrosis after acute infections. Chronic cholestasis, although rare following infections, may lead to dental enamel hypoplasia, failure to thrive, biliary rickets, severe pruritus, and xanthoma.

Table 22–4. Treatment of complications of chronic cholestatic liver disease.

2. Specific Infectious Agents

A. Neonatal Hepatitis B Virus (HBV) Disease

Vertical transmission of HBV may occur at any time during perinatal life. Most cases are acquired from mothers who are asymptomatic carriers of HBV. Although HBV has been found in most body fluids, including breast milk, neonatal transmission occurs primarily from exposure to maternal blood at delivery and only occasionally transplacentally (< 5%–10% of cases). In chronic HB surface antigen (HBsAg)–carrier mothers, neonatal acquisition risk is greatest if the mother: (1) is also HB “e” antigen (HBeAg)–positive and HB “e” antibody (HBeAb)–negative, (2) has high serum levels of hepatitis B core antibody (HBcAb), or (3) has high blood levels of HBV DNA (> 10$^7$ copies/mL). The infant has a 70%–90% chance of acquiring HBV at birth from an HBsAg/HBeAg-positive mother if the infant does not receive prophylaxis. Most infected infants develop a prolonged asymptomatic immune-tolerant phase of HBV infection. Fulminant hepatic necrosis and liver failure rarely
occur in infants. Other patients develop immune active chronic hepatitis with focal hepatocyte necrosis and a mild portal inflammatory response. Chronic hepatitis may persist for years, with serologic evidence of persisting HBeAg and mildly elevated or normal serum aminotransferases. Most infected infants have only mild biochemical evidence, if any, of liver injury and do not appear ill. Most infants remain asymptomatic in an immune-tolerant state of HBV infection; 3%–5% per year develop acute or chronic hepatitis (see section on Hepatitis B).

To prevent perinatal transmission, all infants of mothers who are HBsAg-positive (regardless of HBeAg status) should receive hepatitis B immunoglobulin (HBIG) and hepatitis B vaccine within the first 24 hours after birth and vaccine again at ages 1 and 6 months (see Chapter 10). This prevents HBV infection in 85%–95% of infants. If not given at birth, HBIG can be administered as late as 7 days postpartum as long as the infant has received the vaccine. Universal HBV immunization during infancy is recommended for all infants regardless of maternal HBV status. Universal screening of pregnant women for HbsAg is conducted to determine which infants will also need HBIG. Pregnant women with > 200,000 IU/mL of HBV DNA should be considered for third trimester anti-viral therapy to lower HBV levels and reduce risk for vertical transmission.

B. Neonatal Bacterial Hepatitis

Most bacterial liver infections in newborns are acquired by transplacental invasion from amnionitis with ascending spread from maternal vaginal or cervical infection. Onset is abrupt, usually within 48–72 hours after delivery, with signs of sepsis and often shock. Jaundice appears early with direct hyperbilirubinemia. The most common organisms involved are Escherichia coli, Listeria monocytogenes, and group B streptococci. Neonatal liver abscesses caused by E coli or Staphylococcus aureus may result from omphalitis or umbilical vein catheterization. These infections require specific antibiotics in optimal doses and combinations and, rarely, surgical or radiologic interventional drainage. Deaths are common, but survivors show no long-term consequences of liver disease.

C. Neonatal Jaundice with Urinary Tract Infection

Urinary tract infections typically present with cholestasis between the second and fourth weeks of life. Lethargy, fever, poor appetite, jaundice, and hepatomegaly may be present. Except for mixed hyperbilirubinemia, other liver function tests (LFTs) are only mildly abnormal. Leukocytosis is frequently present, and infection is confirmed by urine culture. The liver impairment is caused by the action of endotoxin and cytokines on bile secretion.

Treatment of the infection leads to resolution of the cholestasis without hepatic sequelae. Metabolic liver diseases, such as galactosemia and tyrosinemia, may present with gram-negative bacterial urinary tract infection and must be excluded.

3. Intrahepatic Cholestasis Resulting From Inborn Errors of Metabolism, Familial, & “Toxic” Causes

Cholestasis caused by specific enzyme deficiencies, other genetic disorders, or certain toxins share findings of intrahepatic cholestasis (jaundice, hepatomegaly, and normal to completely acholic stools). Specific clinical conditions have characteristic clinical signs.

A. Inborn Errors of Metabolism

Establishing the specific diagnosis as early as possible is important because dietary or pharmacologic treatment may be available (Table 22–5). As with other genetic disorders, parents of the affected infant should be offered genetic counseling. For some disorders, prenatal genetic diagnosis is available.

Cholestasis caused by metabolic diseases (eg, galactosemia, hereditary fructose intolerance, and tyrosinemia) is frequently accompanied by vomiting, lethargy, poor feeding, hypoglycemia, or irritability. The infants often appear septic; gram-negative bacteria can be cultured from blood in 25%–50% of symptomatic cases, especially in galactosemia and cholestasis. Neonatal screening programs for galactosemia usually detect the disorder before cholestasis develops. Other metabolic and genetic causes of neonatal intrahepatic cholestasis are outlined in Table 22–5. Treatment of these disorders is discussed in Chapter 36.

B. “Toxic” Causes of Neonatal Cholestasis

1. Neonatal ischemic-hypoxic conditions—Perinatal events that result in hypoperfusion of the gastrointestinal system are sometimes followed within 1–2 weeks by cholestasis. This occurs in infants with birth asphyxia, severe hypoxia, hypoglycemia, shock, and acidosis. When these perinatal conditions develop in association with gastrointestinal lesions, such as ruptured omphalocele, gastrochisis, or necrotizing enterocolitis, a subsequent cholestatic picture is
Table 22–5. Metabolic and genetic causes of neonatal cholestasis.

</tbody>
</table>
common (25%–50% of cases). Mixed hyperbilirubinemia, elevated alkaline phosphatase and γ-glutamyl transpeptidase (GGT) values, and variable elevation of the aminotransferases are common. Stools are seldom persistently acholic.

The mainstays of treatment are choleretics (UDCA), introduction of enteral feedings using special formulas as soon as possible, and nutrient supplementation until the cholestasis resolves (see Table 22–4). As long as no severe intestinal problem or ongoing sepsis is present (eg, short gut syndrome or intestinal failure), resolution of the hepatic abnormalities is the rule, although this may take many weeks.

### 2. Parenteral Nutrition Associated Cholestasis (PNAC)

Cholestasis may develop after 1–2 weeks in premature newborns receiving parenteral nutrition, especially those with necrotizing enterocolitis. Even full-term infants with significant intestinal atresia, resections, or dysmotility (intestinal failure) may develop PNAC, also called Intestinal Failure Associated Cholestasis when it occurs in term infants. Contributing factors include toxicity of intravenous soy lipid emulsions, diminished stimulation of bile flow from prolonged absence of feedings, frequent episodes of bacterial or fungal infection, small intestinal bacterial overgrowth with translocation of intestinal bacteria and their cell wall products, missing nutrients or antioxidants, photooxidation of amino acids, infusion of lipid hydroperoxides or plant sterols, and the "physiologic cholestatic" propensity of the infant. Resolution of innate immune pathways in the liver appears to be involved. Histology of the liver may be identical to that of biliary atresia. Early introduction of feedings has reduced the frequency of this disorder. The prognosis is generally good; however, in infants with intestinal failure occasional cases progress to cirrhosis, liver failure, or hepatoma. These infants may require liver and intestinal, or multivisceral, transplantation. Oral erythromycin as a pro-motility agent may reduce the incidence of cholestasis in very-low-birthweight infants. Substituting intravenous fish oil-based lipid emulsions or multiple constituent lipid emulsions, or reducing the amount of soy-oil-based lipid emulsions may reverse PNAC and prevent need for liver transplantation and delay the need for intestinal transplantation.

### 3. Inspissated bile syndrome

This syndrome is the result of accumulation of bile in canaliculi and in the small- and medium-sized bile ducts in hemolytic disease of the newborn (Rh, ABO) and in some infants receiving parenteral nutrition. The same mechanisms may cause intrinsic obstruction of the common bile duct. An ischemia-reperfusion injury may also contribute to cholestasis in Rh incompatibility. Stools may become acholic and levels of bilirubin, primarily conjugated, may reach 40 mg/dL. If inspissation of bile occurs within the extrahepatic biliary tree, differentiation from biliary atresia may be difficult. Although most cases improve slowly over 2–6 months, persistence of complete cholestasis (acholic stools) for more than 1–2 weeks requires further studies (ultrasonography, liver biopsy) with possible cholangiography. Irrigation of the common bile duct is sometimes necessary to dislodge the obstructing inspissated biliary material.

### 4. Idiopathic Neonatal Hepatitis (Transient Neonatal Cholestasis)

This idiopathic type of cholestatic jaundice, which has a typical liver biopsy appearance, accounts for up to 20%–30% of cases of neonatal intrahepatic cholestasis but is decreasing in frequency as new genetic causes of cholestasis are discovered. The degree of cholestasis is variable, and

the disorder may be indistinguishable from extrahepatic causes in 10% of cases. Viral infections, α₁-antitrypsin deficiency, Alagille syndrome, Niemann-Pick type C disease (NPC), progressive familial intrahepatic cholestasis (PFIC) disorders, citrin deficiency, neonatal hemochromatosis, mitochondrial disorders, and bile acid synthesis defects may present with similar clinical and histologic features and should be excluded. In idiopathic neonatal hepatitis, PFIC types I and II and ARC syndrome, and disease due to bile acid synthesis defects, the GGT levels are normal or low. Electron microscopy of the liver biopsy and genotyping will help distinguish NPC and PFIC. It is likely that a heterozygous state or mild missense mutations for known or yet to be discovered causative genes are responsible for the vast majority of idiopathic cases.

Intrauterine growth retardation, prematurity, poor feeding, emesis, poor growth, and partially or intermittently acholic stools are characteristic. Serious hemorrhage from vitamin K deficiency may also be present. Patients with neonatal lupus erythematosus may present with giant-cell hepatitis; however, thrombocytopenia, rash, or congenital heart block is usually also present.

In cases of suspected idiopathic neonatal hepatitis (diagnosed in the absence of infectious, known genetic, metabolic, and toxic causes), patency of the biliary tree may need to be verified to exclude extrahepatic surgical disorders. HIDA scanning and ultrasonography may be helpful in this regard if stools are acholic. Liver biopsy findings are usually diagnostic after age 6–8 weeks (see Table 22–2), but may be misleading before age 6 weeks as there is overlap with biliary atresia histology. Failure to detect patency of the biliary tree, nondiagnostic liver biopsy findings, or persisting complete cholestasis (acholic stools) are indications for intraoperative cholangiography performed by an experienced surgeon, ERCP, or percutaneous cholecystography. Occasionally, a small but patent (hypoplastic) extrahepatic biliary tree is demonstrated (as in Alagille syndrome). It is probably the result, rather than the cause, of diminished bile flow, so surgical reconstruction of hypoplastic biliary trees in Alagille syndrome should not be attempted.

Therapy should include choleretics, a special formula with medium-chain triglycerides (eg, Pregestimil, Alimentum) or breast milk (if growth is adequate), and supplemental fat-soluble vitamins in water-soluble form (see Table 22–4). This therapy is continued as long as significant cholestasis remains (conjugated bilirubin > 1 mg/dL). Fat-soluble vitamin serum levels and INR should be monitored at regular intervals while supplements are given and repeated at least once after their discontinuation.

Around 80% of patients recover without significant hepatic fibrosis. However, failure to resolve the cholestatic picture by age 6–12 months is associated with progressive liver disease and evolving cirrhosis, most likely caused by known or yet to be defined underlying genetic/metabolic disorder. Liver transplantation has been successful when signs of hepatic decompensation are noted (rising bilirubin, coagulopathy, intractable ascites).

## 5. Paucity of Interlobular Bile Ducts

Forms of intrahepatic cholestasis caused by decreased numbers of interlobular bile ducts (< 0.5 bile ducts per portal tract) may be classified according to whether they are associated with other malformations. Alagille syndrome (syndromic paucity or arteriohepatic dysplasia) is caused by mutations in the gene JAGGED1, located on chromosome 20p, which codes for a ligand of the notch receptor, or more rarely in the gene NOTCH2. Alagille syndrome is recognized by the characteristic facies, which becomes more obvious with age. The forehead is prominent, with deep-set eyes and sometimes hypertelorism. The chin is small and slightly pointed and ears are prominent. The stool color varies with the severity of cholestasis. Pruritus begins by age 6 months. Firm, smooth hepatomegaly may be present or the liver may be of normal size. Cardiac murmurs are present in 95% of patients, and butterfly vertebrae (incomplete fusion of the vertebral body or anterior arch) are present in 50%. Xanthomas develop as hypercholesterolemia becomes a problem.

Conjugated hyperbilirubinemia may be mild to severe (2–15 mg/dL). Serum alkaline phosphatase, GGT, and cholesterol are markedly elevated, especially early in life. Serum bile acids are always elevated, aminotransferases are mildly increased, but clotting factors and other liver proteins are usually normal.

Cardiac involvement includes peripheral pulmonary artery, branch pulmonary artery, or pulmonary valvular stenoses, atrial septal defect, coarctation of the aorta, and tetralogy of Fallot. Up to 10%–15% of patients have intracranial vascular or cystic abnormalities or may develop intracranial hemorrhage or stroke early in childhood.

Eye findings (posterior embryotoxon or a prominent Schwalbe line in 90%) are common and renal abnormalities (dysplastic kidneys, renal tubular ectasia, single kidney, renal tubular acidosis, hematuria) may occur in 40% of patients. Growth retardation with normal to increased levels of growth hormone (growth hormone resistance) is common. Some patients may rarely have pancreatic insufficiency that may contribute to the fat malabsorption. Although variable, the intelligence quotient is frequently low. Hypogonadism with micropenis may be present. A weak, high-pitched voice may develop. Neurologic disorders resulting from vitamin E deficiency (areflexia, ataxia, ophthalmoplegia), which
eventually develop in many unsupplemented children, may be profound.

In the nonsyndromic form, paucity of interlobular bile ducts occurs associated with α1-antitrypsin deficiency, Zellweger syndrome, in association with lymphedema (Aagenaes syndrome), PFIC, cystic fibrosis, CMV or rubella infection, and inborn errors of bile acid metabolism.

High doses (250 mg/kg/day) of cholestyramine may control pruritus, lower cholesterol, and clear xanthomas. UDCA (15–20 mg/kg/day) appears to be more effective and causes fewer side effects than cholestyramine. Rifampicin may also reduce pruritus. Naltrexone (1 mg/kg/day) is occasionally required. Partial external biliary diversion or ileal exclusion surgery may reduce pruritus in about half of severe cases as long as significant hepatic fibrosis is absent. Nutritional therapy to prevent wasting and deficiencies of fat-soluble vitamins is of particular importance because of the severity of cholestasis (see Table 22–4).

Prognosis is more favorable in the syndromic than in the nonsyndromic varieties. In the former, only 30%–40% of patients have severe complications of disease, whereas over 70% of patients with nonsyndromic varieties progress to cirrhosis. Many of this latter group likely have forms of PFIC. In Alagille syndrome, cholestasis may improve by age 2–4 years, with minimal residual hepatic fibrosis. Survival into adulthood despite raised serum bile acids, aminotransferases, and alkaline phosphatase occurs in about 50% of cases. Several patients have developed hepatocellular carcinoma. Hypogonadism has been noted; however, fertility is not often affected. Cardiovascular anomalies and intracranial vascular lesions may shorten life expectancy. Some patients have persistent, severe cholestasis, rendering their quality of life poor. Recurrent bone fractures may result from metabolic bone disease. Liver transplantation has been successfully performed under these circumstances. Intrahepatic hemorrhage, moya moya disease, or stroke may occur in up to 10%–12% of affected children.

**6. Progressive Familial Intrahepatic Cholestasis (PFIC; Byler Disease & Byler Syndrome)**

PFIC is a group of disorders presenting as pruritus, diarrhea, jaundice, fat-soluble vitamin deficiencies, and failure to thrive in the first 6–12 months of life. PFIC type I (Byler disease), caused by biallelic mutations in ATP8B1 coding FIC1, an aminophospholipid floppase, is associated with low to normal serum levels of GGT and cholesterol and elevated levels of bilirubin, aminotransferases, and bile acids. Pancreatitis and hearing loss may develop. Liver biopsy demonstrates cellular cholestasis, sometimes with a paucity of interlobular bile ducts and centrilobular fibrosis that progresses to cirrhosis. Giant cells are absent. Electron microscopy shows diagnostic granular “Byler bile” in canaliculi. Treatment includes administration of UDCA, partial biliary diversion or ileal exclusion if the condition is unresponsive to UDCA, and liver transplantation if unresponsive to these therapies. With partial biliary diversion or ileal exclusion surgery, many patients show improved growth and liver histology, reduction in symptoms and, thus, avoid liver transplantation. Following liver transplantation, chronic diarrhea and fatty liver may complicate recovery.

PFIC type II is caused by biallelic mutations in ABCB11 coding the bile salt export pump (BSEP), the adenosine triphosphate–dependent canalicular bile salt transport protein. These patients are clinically and biochemically similar to PFIC type I patients, but liver histology includes numerous multinucleated “giant cells” and they have higher elevations of AST and ALT. There is an increased incidence of hepatocellular carcinoma in patients with severe ABCB11 mutations. Treatment is similar to PFIC type I although close monitoring for hepatocellular carcinoma is essential. Following liver transplantation, recurrent disease has been described in patients who developed autoimmune-mediated BSEP dysfunction.

PFIC type III is caused by mutations in ABCB4 coding in the multiple drug resistance protein type 3 (MDR3), which encodes a canalicular protein that pumps phospholipid into bile. Serum GGT and bile acid levels are both elevated, bile duct proliferation and portal tract fibrosis are seen in liver biopsies (resembling biliary atresia), and bile phospholipid levels are low. Treatment is similar to that for other forms of PFIC except that partial biliary diversion is not recommended and liver transplantation is inevitable.

PFIC type IV is a low GGT form of neonatal cholestasis caused by mutations in tight junction protein 2 (TJP2) with rapid progression to cirrhosis and need for liver transplantation in early childhood. PFIC type V (FXR deficiency) and type VI (MYO5B deficiency) have recently been described and resemble clinically the other PFICs. About one-third of PFIC patients have negative genotyping for the above genes and most likely have yet-to-be discovered genetic etiologies.

Bile acid synthesis defects are clinically similar to PFIC types I and II, with low serum levels of GGT and cholesterol; however, the serum level of total bile acids is inappropriately normal or low and urine bile acid analysis may identify a synthesis defect. Milder defects cause fat-soluble vitamin deficiency without severe liver disease. Treatment of most
bile acid synthesis defects is with oral cholic acid and for conjugation defects with oral glycocholic acid.

EXTRAHEPATIC NEONATAL CHOLESTASIS

Extrahepatic neonatal cholestasis is characterized by complete and persistent cholestasis (acholic stools) in the first 3 months of life; lack of patency of the extrahepatic biliary tree proved by intraoperative, percutaneous, or endoscopic cholangiography; firm to hard hepatomegaly; and typical features on histologic examination of liver biopsy tissue (see Table 22–2). Causes include biliary atresia, choledochal cyst, spontaneous perforation of the extrahepatic ducts, neonatal sclerosing cholangitis, and intrinsic or extrinsic obstruction of the common duct.

1. Biliary Atresia

   General Considerations

Biliary atresia (BA) is a progressive fibroinflammatory obliteration of the lumen of all, or part of, the extrahepatic biliary tree presenting within the first 3 months of life. BA occurs in 1:6600 (Taiwan)–1:18,000 (Europe) births, and in the United States the incidence is approximately 1:12,000. The incidence is highest in Asians, African Americans, and preterm infants, and there is a slight female predominance. There are three types of BA: isolated BA (84% of cases), BA with at least one malformation but without laterality defects (6%; CV, GI, or GU defects), and BA splenic malformation (BASM) syndrome associated with laterality defects and polysplenia or asplenia (4%–10%). The theories as to the etiology of BA vary based on the type of BA. Evidence obtained from surgically removed remnants of the extrahepatic biliary tree suggests an inflammatory sclerosing cholangiopathy that may have a prenatal onset triggered by either a viral or toxin insult. Recent research supports an autoimmune reaction that is responsible for progressive intrahepatic bile duct injury and fibrosis. In BA with other congenital malformations, the bile duct presumably did not develop normally and is associated with other nonhepatic congenital anomalies. The association of BA with the polysplenia syndrome (heterotaxia, preduodenal portal vein, interruption of the inferior vena cava, polysplenia, and midline liver) and asplenia syndrome supports an embryonic and possible genetic origin of biliary atresia in these cases.

Clinical Findings

A. Symptoms and Signs

All infants with BA will have jaundice that may be noted in the newborn period or by age 2–3 weeks. All jaundiced infants ≥ 2 weeks of age should have serum bilirubin fractionated to determine cholestasis in. Urine stains the diaper; and stools are often pale yellow, gray, or acholic. Firm hepatomegaly is common at diagnosis and infants are at risk for failure to thrive. Symptoms of portal hypertension (splenomegaly, ascites, variceal bleeding) may develop in the first year of life. Pruritus, digital clubbing, bone fractures, and variceal bleeding complications may occur later in childhood.

B. Laboratory Findings and Imaging

No single laboratory test will consistently differentiate BA from other causes of complete obstructive jaundice. Although BA is suggested by persistent elevation of serum GGT or alkaline phosphatase levels in addition to conjugated/direct bilirubin, these findings have also been reported in severe neonatal hepatitis, α1-antitrypsin deficiency, cystic fibrosis, MDR3 deficiency, neonatal sclerosing cholangitis, and bile duct paucity. Furthermore, these tests will not differentiate the location of the obstruction within the extrahepatic system. Generally, the aminotransferases are only moderately elevated in BA and serum albumin and blood clotting factors are normal early in the disease. Ultrasonography of the biliary system should be performed to exclude the presence of choledochal cyst and identify intra-abdominal anomalies associated with BA. In the majority of cases of BA, the gallbladder is not visualized or is small; however, the presence of a normal gallbladder on ultrasound does not exclude BA, and identifying the triangular cord sign is operator dependent. Liver biopsy specimens (particularly if obtained after age 6 weeks) can differentiate intrahepatic causes of cholestasis from BA in over 90% of cases (see Table 22–2).

Differential Diagnosis

The major diagnostic dilemma is distinguishing between this entity and bile duct paucity, genetic and metabolic liver disease (particularly α1-antitrypsin deficiency), choledochal cyst, neonatal sclerosing cholangitis, or intrinsic bile duct obstruction (inspissated bile syndrome). Although spontaneous perforation of extrahepatic bile ducts leads to jaundice and acholic stools, the infants in such cases are usually quite ill with chemical peritonitis from biliary ascites.

If the diagnosis of BA cannot be excluded by the diagnostic evaluation and percutaneous liver biopsy, an intraoperative cholangiogram should be performed as soon as possible to determine if BA is present to facilitate construction of a port-enterostomy immediately if BA is found.
Radiographic visualization of cholangiographic contrast in the duodenum excludes obstruction to the distal extrahepatic ducts. In the majority of cases of BA, the entire extrahepatic biliary system is obstructed and no cholangiographic contrast will be visible.

**Treatment**

In the absence of surgical correction or transplantation, biliary cirrhosis, hepatic failure, and death occur uniformly by age 18–24 months.

The standard procedure at the time of diagnosis of BA is the hepatopportoenterostomy (Kasai procedure). Occasionally, portocholecystostomy (gallbladder Kasai procedure) may be performed if the gallbladder is present and the passage from it to the duodenum is patent. These procedures are best done in specialized centers where experienced surgical, pediatric, and nursing personnel are available. Surgery should be performed as early as possible (ideally before 45 days of life); the Kasai procedure should generally not be undertaken in infants older than age 4 months, because the likelihood of bile drainage at this age is very low. Orthotopic liver transplantation is now indicated for patients who do not undergo the Kasai procedure, who fail to drain bile after the Kasai procedure, or who progress to end-stage biliary cirrhosis despite surgical treatment. Timing of liver transplant evaluation and care prior to transplant has recently been reviewed.

Supportive medical treatment consists of vitamin and caloric support (vitamins A, D, E, and K supplements and formulas containing high amounts of medium-chain triglycerides [Pregestimil or Alimentum]) (see Table 22–4). Nasogastric tube feedings or parenteral nutrition may be required in patients failing oral caloric supplementation. Monitoring of serum fat-soluble vitamin levels is essential to ensure adequate supplementation. Ursodeoxycholic acid (UDCA) as a choleretic agent is routinely given post-Kasai and continued up to 3 years of age. UDCA should not be used in the setting of a “failed Kasai” whereby bile flow is not established, as UDCA in this setting is potentially hepatotoxic. Suspected ascending cholangitis (based on fever, jaundice, acholic stools, abdominal pain, elevated liver enzymes) should be treated promptly with trimethoprim-sulfamethoxazole broad-spectrum antibiotics. Antibiotic prophylaxis may reduce the recurrence rate of cholangitis. Ascites can be managed initially with spironolactone; furosemide is added in severe or unresponsive cases. There is no therapy that prevents the progression of biliary disease and portal fibrosis that occurs in the majority of patients post-Kasai, including the use of corticosteroids.

**Prognosis**

In general, outcomes of post-Kasai include failure to reestablish bile flow in one-third and improvement in bile flow in up to two-thirds of patients. Approximately 50% of BA patients will require liver transplantation in the first 2 years of life. The best predictor of the need for liver transplant in the first 2 years is the total serum bilirubin value at 3 months post-Kasai: if the total bilirubin is < 2 mg/dL then a it is unlikely that child will need transplant in the first 2 years; if the bilirubin is > 6 mg/dL, then a liver transplant will likely be necessary in the first 2 years. Even in the setting of reestablished bile flow following Kasai surgery, the majority of patients will progress to biliary cirrhosis and need a liver transplantation at some point in childhood (~ 80% of all BA patients). Death is usually caused by liver failure, sepsis, intractable variceal bleeding, or respiratory failure secondary to intractable ascites. Esophageal variceal hemorrhage develops in 40% of patients, yet terminal hemorrhage is unusual. Occasional long-term survivors develop hepatopulmonary syndrome (intrapulmonary right to left shunting of blood resulting in hypoxia) or portopulmonary hypertension (pulmonary arterial hypertension in patients with portal hypertension). Liver transplantation is indicated for all of the above-noted complications and long-term survival post-transplant is ~80%–90%.

2. Choledochal Cyst

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Abnormal abdominal ultrasound with cyst of the biliary tree.

**Clinical Features**

A. Symptoms and Signs

Choledochal cysts (CDC) are cystic lesions of all or part of the extrahepatic biliary system, which in rare cases can include the intrahepatic bile duct branches. Abdominal ultrasound imaging will detect all cases of CDC. In most cases, the clinical manifestations, basic laboratory findings, and histopathologic features on liver biopsy are indistinguishable from those associated with biliary atresia.
Rarely neonatal CDC may be associated with atresia of the distal common duct, termed “cystic biliary atresia,” and prompt intervention with Kasai portoenterostomy is warranted. In older children, CDC presents as recurrent episodes of right upper quadrant abdominal pain, fevers, vomiting, obstructive jaundice, pancreatitis, or as a right abdominal mass. Infants and children with CDC are at increased risk for developing bacterial cholangitis. CDC represent only 2%–5% of cases of extrahepatic neonatal cholestasis; the incidence is higher in girls and patients of Asian descent.

B. Imaging Studies

Ultrasonography or magnetic resonance imaging (MRI) reveals the presence of a CDC.

Treatment

Timely surgery is indicated once abnormalities in clotting factors have been corrected and bacterial cholangitis, if present, has been treated with intravenous antibiotics. Excision of the cyst and choledocho–Roux-en-Y jejunal anastomosis are recommended. In some cases, because of technical problems, only the mucosa of the cyst can be removed with jejunal anastomosis to the proximal bile duct. Anastomosis of cyst to jejunum or duodenum is not recommended due to the continued risks of cholangitis and bile duct carcinoma (cholangiocarcinoma).

Prognosis

The prognosis depends on the presence or absence of associated evidence of atresia and the appearance of the intrahepatic ducts. If atresia is found, the prognosis is similar to that described in the preceding section. If an isolated extrahepatic cyst is encountered, the outcome is generally excellent, with resolution of the jaundice and return to normal liver architecture. However, bouts of ascending cholangitis may occur, particularly if intrahepatic cysts are present or stricture of the anastomotic site develops. The risk of cholangiocarcinoma developing within the cyst is about 5%–15% in adulthood; therefore, cystectomy or excision of cyst mucosa should be undertaken whenever possible.

3. Spontaneous Perforation of the Extrahepatic Bile Ducts

The sudden appearance of obstructive jaundice, acholic stools, and abdominal enlargement with ascites in a sick newborn is suggestive of this condition. The liver is usually normal in size, and a yellow-green discoloration can often be discerned under the umbilicus or in the scrotum. In 24% of cases, stones or sludge obstructs the common bile duct. HIDA scan or ERCP shows leakage from the biliary tree, and ultrasonography confirms ascites or fluid around the bile duct.

Treatment is surgical. Simple drainage, without attempts at oversewing the perforation, is sufficient in primary perforations. A diversion anastomosis is constructed in cases associated with choledochal cyst or stenosis. The prognosis is generally good.

OTHER NEONATAL HYPERBILIRUBINEMIC CONDITIONS (NONCHOLESTATIC NONHEMOLYTIC)

Two other groups of disorders are associated with hyperbilirubinemia: (1) unconjugated hyperbilirubinemia is characteristic of breast milk jaundice, congenital hypothyroidism, upper intestinal obstruction, Gilbert disease, Crigler-Najjar syndrome, and drug-induced hyperbilirubinemia; and (2) conjugated noncholestatic hyperbilirubinemia is characteristic of the Dubin-Johnson syndrome and Rotor syndrome.

1. Unconjugated Hyperbilirubinemia

A. Breast Milk Jaundice

Persistent elevation of the indirect bilirubin fraction may occur in up to 35% breast-fed infants. Enhanced β-glucuronidase activity in breast milk is one factor that increases absorption of unconjugated bilirubin. Substances (eg, L-aspartic acid) in casein hydrolysate formulas inhibit this enzyme. The increased enterohepatic shunting of unconjugated bilirubin exceeds the normal conjugating capacity in the liver of these infants. The mutation for Gilbert syndrome (UDP-glucuronyltransferase 1A1 [UGT1A1]) predisposes to breast milk jaundice and to more prolonged jaundice. Neonates who carry the 211 and 388 variants in the UGT1A1 and OATP 2 genes, respectively, or the UGT1A1*6 allele and feed with breast milk, are at high risk to develop severe hyperbilirubinemia. Low volumes of ingested breast milk may also contribute to jaundice in the first week of life. Finally, breast milk may suppress UGT1A1 expression in the infant’s intestines which may also lead to unconjugated hyperbilirubinemia.

Hyperbilirubinemia does not usually exceed 20 mg/dL, with most cases in the range of 10–15 mg/dL. Jaundice is noticeable by the fifth to seventh day of breast-feeding.
It may accentuate the underlying physiologic jaundice—especially early, when total fluid intake may be less than optimal. Except for jaundice, the physical examination is normal; urine does not stain the diaper, and the stools are golden yellow.

The jaundice peaks before the third week of life and clears before age 3 months in almost all infants, even when breast-feeding is continued. All infants who remain jaundiced past age 2–3 weeks should have measurement of conjugated bilirubin to exclude cholestasis and hepatobiliary disease.

Kernicterus has rarely been reported in association with this condition. In special situations, breast-feeding may be discontinued temporarily and replaced by formula feedings for 2–3 days until serum bilirubin decreases by 2–8 mg/dL. Cow’s milk formulas inhibit the intestinal reabsorption of unconjugated bilirubin. When breast-feeding is reinstalled, the serum bilirubin may increase slightly, but not to the previous level. Phototherapy is not indicated in the healthy full-term infant with this condition unless bilirubin levels meet high-risk levels as defined by the American Academy of Pediatrics.

B. Congenital Hypothyroidism

Although the differential diagnosis of indirect hyperbilirubinemia should always include congenital hypothyroidism, the diagnosis is usually suggested by clinical and physical clues or, more commonly, from the newborn screening results. The jaundice clears quickly with replacement thyroid hormone therapy, although the mechanism is unclear. Hypopituitarism can also present with neonatal cholestasis.

C. Upper Intestinal Obstruction

The association of indirect hyperbilirubinemia with high intestinal obstruction (eg, duodenal atresia, annular pancreas, pyloric stenosis) in the newborn has been observed repeatedly; the mechanism is unknown. Diminished levels of hepatic glucuronyl transferase are found on liver biopsy in pyloric stenosis, and genetic studies suggest that this indirect hyperbilirubinemia may be an early sign of Gilbert syndrome.

Treatment is that of the underlying obstructive condition (usually surgical). Jaundice disappears once adequate nutrition is achieved.

D. Gilbert Syndrome

Gilbert syndrome is a common form of familial hyperbilirubinemia present in 3%–7% of the population. It is associated with a partial reduction of hepatic bilirubin uridine diphosphate-glucuronyl transferase activity. Affected infants may have more rapid increase in jaundice in the newborn period, accentuated breast milk jaundice, and jaundice with intestinal obstruction. During puberty and beyond, mild fluctuating jaundice, especially with illness and vague constitutional symptoms, is common. Shortened red blood cell survival in some patients is thought to be caused by reduced activity of enzymes involved in heme biosynthesis (protoporphyrinogen oxidase). Reduction of hyperbilirubinemia has been achieved in patients by administration of phenobarbital (5–8 mg/kg/day), although this therapy is not justified.

The disease is inherited as an abnormality of the promoter region of uridine diphosphate-glucuronyl transferase-1 (UDGTT1) coded by UGT1A1; however, another factor appears to be necessary for disease expression. The homozygous (16%) and heterozygous states (40%) are common. Males are affected more often than females (4:1) for reasons that are not clear. Serum unconjugated bilirubin is generally less than 3–6 mg/dL, although unusual cases may exceed 8 mg/dL. The findings on liver biopsy and most LFTs are normal. An increase of 1.4 mg/dL or more in the level of unconjugated bilirubin after a 2-day fast (300 kcal/day) is consistent with the diagnosis of Gilbert syndrome. Gilbert syndrome, conferred by the donor liver, can occur following liver transplantation. Genetic testing is available but rarely needed. No treatment is necessary.
E. Crigler-Najjar Syndrome

Infants with type 1 Crigler-Najjar syndrome usually develop rapid severe unconjugated hyperbilirubinemia (> 30–40 mg/dL) with neurologic consequences (kernicterus). Consanguinity is often present. Prompt recognition of this entity and treatment with exchange transfusions are required, followed by phototherapy. Some patients have no neurologic signs until adolescence or early adulthood, at which time deterioration may occur suddenly. For diagnosis of this condition, it may be useful to obtain a duodenal bile specimen, which characteristically will be colorless and contain a predominance of unconjugated bilirubin, small amounts of monoglucuronide and diglucuronide conjugates of bilirubin. Phenobarbital administration does not significantly alter these findings, nor does it lower serum bilirubin levels. The deficiency in UGT1A1 is inherited in an autosomal recessive pattern. Genetic testing of UGT1A1 is definitive. A combination of aggressive phototherapy and cholestyramine may keep bilirubin levels below 25 mg/dL. The use of tin protoporphyrin or tin mesoporphyrin remains experimental. Oral ursodeoxycholic acid (UDCA) is available. No treatment is needed for either condition. Choleretic agents (eg, UDCA) may help reduce the cholestasis in infants with Dubin-Johnson syndrome.

F. Drug-Induced Hyperbilirubinemia

Vitamin K₃ (menadiol) may elevate indirect bilirubin levels by causing hemolysis. Vitamin K₃ (phytonadione) can be used safely in neonates. Carbamazepine can cause conjugated hyperbilirubinemia in infancy. Rifampin and antiretroviral protease inhibitors (atazanavir) may cause unconjugated hyperbilirubinemia. Pancuronium bromide and chloral hydrate have been implicated in causing neonatal jaundice. Other drugs (eg, ceftriaxone, sulfonamides) may displace bilirubin from albumin, potentially increasing the risk of kernicterus—especially in the sick premature infant.

2. Conjugated Noncholestatic Hyperbilirubinemia (Dubin-Johnson Syndrome & Rotor Syndrome)

These diagnoses are suspected when persistent or recurrent conjugated hyperbilirubinemia and jaundice occur and liver function tests are normal. The basic defect in Dubin-Johnson syndrome is in the multiple organic anion transport protein 2 (MRP2) of the bile canalculus, causing impaired hepatocyte excretion of conjugated bilirubin into bile. A variable degree of impairment in uptake and conjugation complicates the clinical picture. Transmission is autosomal recessive, so a positive family history is occasionally obtained. In Rotor syndrome, the defect lies in hepatic uptake and storage of bilirubin. OATP1B1 (coded by SLCO1B1) and OATP1B3 (SLCO1B3) are the two transporters that are deficient. Bile acids are metabolized normally, so that cholestasis does not occur. Bilirubin values range from 2 to 5 mg/dL, and other LFTs are normal.

In Rotor syndrome, the liver is normal; in Dubin-Johnson syndrome, it is darkly pigmented on gross inspection and may be enlarged. Microscopic examination reveals numerous dark-brown pigment granules consisting of polymers of epinephrine metabolites, especially in the centrilobular regions. However, the amount of pigment varies within families, and some jaundiced family members may have no demonstrable pigmentation in the liver. Otherwise, the liver is histologically normal. Oral cholecystography fails to visualize the gallbladder in Dubin-Johnson syndrome, but is normal in Rotor syndrome. Differences in the excretion patterns of bromosulphathalein, in results of HIDA cholescintigraphy, in urinary coproporphyrin I and III levels, and in the serum pattern of monoglucuronide and diglucuronide conjugates of bilirubin can help distinguish between these two conditions. Clinical genotyping of MRP2, SLCO1B1, and SLCO1B3 is available. No treatment is needed for either condition. Choleretic agents (eg, UDCA) may help reduce the cholestasis in infants with Dubin-Johnson syndrome.

Kepler D: The roles of MRP2, MRP3, OATP1B1, and OATP1B3 in conjugated hyperbilirubinemia. Drug Metab Dispos 2014 Apr; 42(4):561–565 [PMID: 24459177].
HEPATITIS A

**Essentials of Diagnosis & Typical Features**

- Gastrointestinal upset (anorexia, vomiting, diarrhea).
- Jaundice.
- Liver tenderness and enlargement.
- Abnormal LFTs.
- Local epidemic of hepatitis A infection.
- Positive anti–hepatitis A virus (HAV) IgM antibody.

**Pathogenesis**

Hepatitis A virus (HAV) infection occurs in both epidemic and sporadic fashion and is transmitted by the fecal oral route (Table 22–6). HAV viral particles are found in stool during the acute phase of hepatitis A infection. Epidemic outbreaks are caused by contaminated food or water supplies, including by food handlers, while sporadic cases usually result from contact with an infected individual. Transmission through blood products obtained during the viremic phase is a rare event, although it has occurred in a newborn nursery.

**Prevention**

Isolation of an infected patient during initial phases of illness is indicated, although most patients with hepatitis A are noninfectious by the time the disease becomes overt. Stool, diapers, and other fecally stained clothing should be handled with care for 1 week after the appearance of jaundice.

Passive-active immunization of exposed susceptible persons younger than 12 months or older than 40 years: anyone who is immunocompromised or who has chronic liver disease is recommended with immune globulin, 0.02 mL/kg intramuscularly. Illness is prevented in > 85% of individuals if immune globulin is given within 2 weeks of exposure. For individuals 12 months to 40 years old, HAV vaccine is recommended following exposure. Infants younger than 12 months traveling to endemic disease areas should receive HAV vaccine or 0.02 or 0.06 mL/kg (for trip > 3 months) of immune globulin as prophylaxis. Older individuals should receive the HAV vaccine. All children older than 12 months with chronic liver disease should receive two doses of HAV vaccine 6 months apart. It is also currently recommended that all children 12–18 months of age receive HAV vaccination in the United States. If an emigrant child from an

Antibody to HAV appears within 1–4 weeks of clinical symptoms. Although the great majority of children with infectious hepatitis are asymptomatic or have mild disease and recover completely, some will develop fulminant hepatitis leading to death or requiring liver transplantation.

**Clinical Findings**

**A. History**

Historical risk factors may include direct exposure to a previously jaundiced individual or recently arrived individual from a high prevalence country, consumption of seafood, contaminated water or imported fruits or vegetables, attendance in a day care center, or recent travel to an area of endemic infection. Following an incubation period of 15–40 days, nonspecific symptoms usually precede the development of jaundice by 5–10 days. In developing countries, hepatitis A is common and most children are exposed to HAV by age 10 years, while only 20% are exposed by age 20 years in developed countries.

**B. Symptoms and Signs**

The overt form of the disease is easily recognized by the clinical manifestations. However, two-thirds of children are asymptomatic, and two-thirds of symptomatic children are anicteric. Therefore, the presenting symptoms in children with HAV often resemble gastroenteritis. Fever, anorexia, vomiting, headache, and abdominal pain are typical and dark urine precedes jaundice, which peaks in 1–2 weeks and then begins to subside. The stools may become light- or clay-colored. Clinical improvement can occur as jaundice develops. Tender hepatomegaly and jaundice are typically present in symptomatic children; splenomegaly is variable.

**C. Laboratory Findings**

Serum aminotransferases and conjugated and unconjugated bilirubin levels are elevated. Although unusual, hypoalbuminemia, hypoglycemia, and marked prolongation of PT (international normalized ratio [INR] > 2.0) are serious prognostic findings. Diagnosis is made by a positive anti-HAV IgM, whereas anti-HAV IgG persists after recovery.

Percutaneous liver biopsy is rarely indicated. “Balloon cells” and acidophilic bodies are characteristic histologic findings. Liver cell necrosis may be diffuse or focal, with accompanying infiltration of inflammatory cells containing polymorphonuclear leukocytes, lymphocytes, macrophages, and plasma cells, particularly in portal areas. Some bile duct proliferation may be seen in the perilobular portal areas alongside areas of bile stasis. Regenerative liver cells and proliferation of reticuloendothelial cells are present. Occasionally massive hepatocyte necrosis portends a poor prognosis.

**Differential Diagnosis**

Before jaundice appears, the symptoms are those of nonspecific viral enteritis. Other diseases with somewhat similar onset include pancreatitis, infectious mononucleosis, leptospirosis, drug-induced hepatitis, Wilson disease, autoimmune hepatitis (AIH), and infection with other hepatitis viruses. Acquired CMV disease may also mimic HAV, although lymphadenopathy is usually present in the former.

**Treatment**

No specific treatment measures are required although bed rest is reasonable for the child who appears ill. Sedatives and corticosteroids should be avoided. During the icteric phase, lower-fat foods may diminish gastrointestinal symptoms but do not affect overall outcome. Drugs and elective surgery should be avoided. Hospitalization is recommended for children with coagulopathy, encephalopathy, or severe vomiting. Hospitalization rates for hepatitis A have decreased over the last decade, with those who require hospitalization being older adults or those with concurrent other liver disease and/or comorbid conditions.
**Prognosis**

Around 99% of children recover without sequelae. Persons with underlying chronic liver disease have an increased risk of death. In rare cases of acute liver failure due to HAV hepatitis, the patient may die within days to weeks or require evaluation for liver transplantation. The prognosis is poor if hepatic coma or ascites develop; liver transplantation is indicated under these circumstances and is life-saving. Incomplete resolution can cause a prolonged hepatitis, but resolution invariably occurs without long-term hepatic sequelae. Rare cases of aplastic anemia following acute infectious hepatitis have been reported. A benign relapse of symptoms may occur in 10%–15% of cases after 6–10 weeks of apparent resolution.

**Pathophysiology**

The HBV particle is composed of a core that is found in the nucleus of infected liver cells and a double outer shell (surface antigen or HBsAg). The nomenclature for the viral antigens and antibodies is found in the table of abbreviations. HBeAg, a truncated soluble form of HBeAg, correlates with active virus replication. Persistence of HBeAg is a marker of infectivity, whereas the appearance of anti-HBe generally implies a lower level of viral replication. However, HBV mutant viruses (precore mutant) may replicate with negative HBeAg tests and positive tests for anti-HBe antibody (HBeAg-negative chronic hepatitis). Such cases are associated with a more virulent form of hepatitis. Circulating HBV DNA (measured by PCR) also indicates viral replication.

**Prevention**

HBV vaccination is the preferred method for prevention. Universal immunization of all infants born in the United States is now recommended, as it is in most other countries. Other control methods include screening of blood donors and pregnant women, use of properly sterilized needles and surgical equipment, avoidance of sexual contact with carriers, general adoption of safe sex practices, and vaccination of household contacts, sexual partners, medical personnel, and those at high risk. For postexposure prophylaxis, HBV vaccine is given alone (see Chapter 10) or together with administration of hepatitis B immune globulin (HBIG) (0.06 mL/kg intramuscularly, given as soon as possible after exposure, up to 7 days). The risk of vertical transmission is dramatically reduced with the combination of newborn vaccination and HBIG administration. For infected pregnant women with high viral loads, use of oral antivirals in the last half of pregnancy combined with postdelivery prophylaxis can further reduce perinatal prophylaxis failures from 5% to 1.5%.

**Clinical Findings**

**A. Symptoms and Signs**

Most infants and young children are asymptomatic, especially if the infection is acquired vertically. Symptoms of acute HBV infection may include a slight fever, malaise, and mild gastrointestinal upset. Visible jaundice is usually the first significant finding and is accompanied by darkening of the urine and pale or clay-colored stools. Hepatomegaly is frequently present. Rare presentations include immune complex mediated rash, arthritis or glomerulonephritis or nephrotic syndrome.

**B. Laboratory Findings**

The diagnosis of acute HBV infection is confirmed by the presence of HBsAg and anti-HBc IgM. Recovery from acute infection is accompanied by HBsAg clearance and
appearance of anti-HBs and anti-HBc IgG. Individuals who are immune by vaccination are positive for anti-HBs, but negative for anti-HBc IgG. Chronic infection is defined as the presence of HBsAg for at least 6 months. Vertical transmission to newborns is documented by positive HBsAg. LFT results are similar to those discussed earlier for hepatitis A. Liver biopsy is most useful in chronic infection to determine the degree of fibrosis and inflammation. Renal involvement may be suspected on the basis of urinary findings suggesting glomerulonephritis or nephrotic syndrome. The various phases of chronic HBV infection are shown in Table 22–7.

### Differential Diagnosis

The differentiation between HAV and HBV disease is aided by a history of parenteral exposure, an HBsAg-positive parent, or an unusually long period of incubation. HBV and hepatitis C virus (HCV) infection or Epstein-Barr virus (EBV) infection are differentiated serologically. The history may suggest a drug-induced hepatitis, especially if a serum sickness prodrome is reported. Autoimmune hepatitis Wilson disease, hemochromatosis, nonalcoholic fatty liver disease (NAFLD), or α1-antitrypsin deficiency.

### Treatment

Supportive measures are used during the active symptomatic stage of acute HBV infection. Corticosteroids are contraindicated. No other treatment is needed for acute HBV infection. For acute infection complicated by acute liver failure, nucleos(t)ide therapy may be helpful. For patients with chronic infection who persist in the immunoreactive phase for more than 6 months or with HBeAg-negative chronic hepatitis, there are currently several approved treatment options in the United States. Treatment with α-interferon (5–6 million U/m² of body surface area injected subcutaneously three times a week for 4–6 months) inhibits viral replication in 30%–40% of patients, normalizes the ALT level, and leads to the disappearance of HBeAg and the appearance of anti-HBe. Side effects are common. Younger children may respond better than older children. Orally administered nucleoside analog therapy includes lamivudine (3 mg/kg/day up to 100 mg/day) and entecavir (0.15–1 mg daily depending on age and weight and prior lamivudine use) for children < 2 years old, or adefovir (10 mg/day) or tenofovir disoproxil fumarate (300 mg/day) for children > 12 years old, and entecavir (0.5 or 1 mg once daily) or telbivudine (600 mg once daily) for children > 16 years old and leads to a successful response in 25%–75% of treated children, with minimal side effects, but may require long-term treatment. However, resistant virus can emerge, more frequently with lamivudine and much less with entecavir and tenofovir. Pegylated interferon, additional oral antiviral agents (with much lower rates of viral resistance), and combination therapy are promising options being tested in children. Immunotolerant children and chronic carriers do not respond to therapy. Liver transplantation is successful in acute liver failure due to hepatitis B; however, reinfection is common following liver transplantation for chronic hepatitis B unless long-term HBIG or antivirals are used.

### Prognosis

The prognosis for acute HBV infection is good in older children, although acute liver failure (< 0.1%) or chronic hepatitis and cirrhosis (up to 10%) may supervene. The course of the acute disease is variable, but jaundice seldom persists for more than 2 weeks. HBsAg disappears in 95% of cases at the time of clinical recovery. Individuals who have cleared HBV (HBsAg negative, anti-HBc IgG positive) are at risk for reactivation of HBV infection with significant immunosuppression (eg, chemotherapy). Chronic infection is particularly common in children with vertical transmission, Down syndrome, or leukemia, and in those undergoing chronic hemodialysis. Persistence of neonatally acquired HBsAg occurs in 70%–90% of infants without immunoprophylaxis or vaccination. The presence of HBeAg in the HBsAg carrier indicates ongoing viral replication. However, 1%–2% of children infected at birth will show spontaneous seroconversion of HBeAg each year. If HBV infection is acquired later in childhood, HBV is cleared and recovery occurs in 90%–95% of patients. Chronic HBV disease predisposes the patient to development of hepatocellular carcinoma. Once chronic HBV infection is established,
surveillance for development of hepatocellular carcinoma with serum α-fetoprotein is performed biannually and ultrasonography every 1–3 years. Routine HBV vaccination of newborns in endemic countries has reduced the incidence of acute liver failure, chronic hepatitis, and hepatocellular carcinoma in children.

HEPATITIS C

General Considerations

Hepatitis C virus (HCV) is the most common cause of non-B chronic hepatitis (see Table 22–6). HCV is a single-stranded RNA flavivirus with at least seven genotypes. Risk factors in adults and adolescents include illicit use of intravenous drugs, occupational or sexual exposure and a history of transfusion of blood products prior to 1992. Most cases in children are associated with transmission from an infected mother (vertical transmission) or rarely from other household contacts, and in adolescents from IV drug use or sexual contact. Vertical transmission from HCV-infected mothers occurs more commonly with mothers who are HIV-positive (15%–20%) compared with those who are HIV-negative (5%–6%). Approximately, 0.2% of children, 0.4% of adolescents, and 1.5% of adults in the United States have serologic evidence of infection.

Prevention

At present, the only effective means of prevention is avoidance of exposure through elimination of risk-taking behaviors such as illicit use of intravenous drugs. There is no effective prevention for vertical transmission, but avoidance of fetal scalp monitoring in infant of mothers with HCV has been suggested. Elective Caesarean section is not recommended for HCV-monoinfected women, as it confers no reduction in the rate of mother-to-infant HCV transmission. Breastfeeding does not promote HCV transmission from mother to infant. It is advised to avoid breast-feeding if the nipples are bleeding, if mastitis is present or if the mother is experiencing a flare of hepatitis with jaundice postpartum. There is no vaccine, and no benefit from using immune globulin in infants born to infected mothers.

Clinical Findings

A. Symptoms and Signs

The majority of childhood cases, especially those acquired vertically, are asymptomatic despite development of chronic hepatitis. The incubation period is 1–5 months, with insidious onset of symptoms. Flu-like prodromal symptoms and jaundice occur in less than 25% of cases. Hepatosplenomegaly may or may not be evident. Ascites, clubbing, palmar erythema, or spider angiomas are rare and indicate progression to cirrhosis. In adults, chronic HCV infection has been associated with mixed cryoglobulinemia, polyarteritis nodosa, a sicca-like syndrome, and membranoproliferative glomerulonephritis, as well as hepatocellular carcinoma.

B. Laboratory Findings

Since anti-HCV IgG crosses the placenta, testing anti-HCV IgG is not informative until the infant is 18 months old, at which time antibody testing should be performed. Patients older than 18 months with positive anti-HCV IgG should have subsequent testing for serum HCV RNA in order to determine active infection. Serum HCV RNA can be tested prior to 18 months of age, but should not be tested before 2 months old. If serum HCV RNA is positive in infancy, it should be rechecked when the infant is 12 months of age in order to determine presence of chronic infection. Fluctuating mild to moderate elevations of aminotransferases over long periods are characteristic of chronic HCV infection; however, normal aminotransferases are common in children. Cirrhosis in adults generally requires 20–30 years of chronic HCV infection, but it has occasionally developed sooner in children.

Differential Diagnosis

HCV disease should be distinguished from HAV and HBV disease by serologic testing. Other causes of chronic hepatitis in children should be considered, including Wilson disease, α1-antitrypsin deficiency, autoimmune hepatitis, primary sclerosing cholangitis, drug-induced hepatitis, or steatohepatitis.

Treatment

The treatment for chronic HCV has rapidly changed in the past decade and treatment for adults with direct-acting antiviral therapies (DAA) for 12–24 weeks has resulted in HCV eradication rates of more than 90%. Double therapy in adults is rapidly evolving and typically includes a non-structural protein 5B (NS5B) polymerase inhibitor like sofosbuvir or dasabuvir, plus either an NS5A inhibitor like ledipasvir or elbasvir, or an NS3/4a protease inhibitor like simeprevir or grazoprevir, both administered orally. Despite the advances in treatment options for adults with HCV, at present, the only approved therapy for treatment of children with chronic HCV remains subcutaneous injections of pegylated interferon-α and oral ribavirin. The sustained virological response rates of this therapy is only 40% in genotype 1 (most common in the United States)
and approximately 80% for genotypes 2 and 3. Clinical trials of DAA drugs in children are ongoing. If the child with chronic HCV has mild disease, it seems prudent to wait for the highly efficacious oral therapies to be approved. End-stage liver disease secondary to HCV responds well to liver transplantation, although reinfection of the transplanted liver is very common; the new DAA therapies appear to be effective at eradicating HCV post-liver transplant as well. A website provides up-to-date guidance for suggested therapies in this era of rapidly evolving approval of new drugs for HCV.

**Prognosis**

Following an acute infection with HCV, 70%–80% of adults and older children develop a chronic infection. Around 20% adults with chronic HCV develop cirrhosis by 30 years. Infants infected by vertical transmission have a high rate of spontaneous resolution approaching 25%–40%. Most have spontaneous resolution by 24 months of age, but some may have spontaneous resolution as late as 7 years after vertical infection. The majority of children with chronic HCV have mild inflammation and fibrosis on liver biopsy, although cirrhosis may develop rapidly in rare cases. Limited 30-year follow-up of infants exposed to HCV by transfusion suggests a lower rate of progression to cirrhosis compared to adults. The prognosis for infants infected at birth with concomitant HIV infection is unknown, but the course appears benign for the first 10 years of life.

**HEPATITIS D (DELTA AGENT)**

The hepatitis D virus (HDV) is a 36-nm defective virus that requires the presence of HBsAg to be infectious (see Table 22–6). Thus, HDV infection can occur only in the presence of HBV infection. Transmission is by parenteral exposure or intimate contact. HDV is rare in North America, but common in Africa, South America, Turkey, Mongolia, southern Italy, and Russia. HDV can infect simultaneously with HBV, causing acute hepatitis, or can superinfect a patient with chronic HBV infection, predisposing the individual to chronic hepatitis or fulminant hepatitis. In children, the association between chronic HDV coinfection with HBV and chronic hepatitis and cirrhosis is strong. Vertical HDV transmission is rare. HDV can be detected by anti-HDV IgG, which indicates active or previous infection; active infection is confirmed by detecting HDV RNA by PCR or by detecting HDV IgM antibody. Treatment is limited to interferon therapy but new treatments are being explored.

**HEPATITIS E**

Hepatitis E virus (HEV) infection causes, acute hepatitis (see Table 22–6). The World Health Organization estimates that one-third of the world’s population has been exposed to HEV. Epidemics have occurred on most continents, but only sporadic cases have been reported in the United States and Europe. The routes of HEV transmission include fecal-oral (consumption of contaminated water and food), vertical, person-to-person and, rarely, parenteral transmission. The majority of cases are asymptomatic; if symptomatic, the clinical manifestations resemble those of HAV infection. HEV infection in pregnancy is associated with a high mortality (10%–20%), particularly when acquired in the third trimester. HEV infection in individuals with chronic liver disease can cause acute deterioration. Immunocompromised individuals infected with HEV are at increased risk for the development of chronic infection, with higher rates of acute liver failure and rapid onset of cirrhosis. Diagnosis is established by detecting anti-HEV IgM antibody or by HEV PCR. There is no effective treatment.

**OTHER HEPATITIS VIRUSES**

Other viruses may cause acute liver failure (ALF) or severe hepatitis in children, in some cases in association with aplastic anemia. Aplastic anemia occurs in a small proportion of patients recovering from hepatitis and in 10%–20% of those undergoing liver transplantation for ALF of unknown etiology. Parvovirus has been associated with severe hepatitis; the prognosis is relatively good in children. Infectious mononucleosis (EBV) is commonly associated with acute hepatitis and rare cases of EBV-associated ALF have been reported. Primary EBV infection in an immunocompromised solid organ transplant recipient may result in a lymphoproliferative disorder. Cytomegalovirus, adenovirus, herpes simplex virus, HHV-6, influenza A and B, HIV, brucella, Q-fever, and leptospirosis are other infectious causes of acute hepatitis or liver failure.

**ACUTE LIVER FAILURE**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Acute hepatitis with deepening jaundice.
- Extreme elevation of AST and ALT.
- Prolonged PT and INR.
- Encephalopathy and cerebral edema.
- Asterixis and fetor hepaticus.

**General Considerations**

Acute liver failure (ALF) is defined as acute liver dysfunction associated with significant hepatic synthetic dysfunction evidenced by vitamin K–resistant coagulopathy (INR > 2.0) within 8 weeks of onset of liver injury. This is often associated with encephalopathy, but in young children, encephalopathy may be difficult to detect. Without liver transplantation, mortality approaches 40% in children. In many cases, an identifiable cause is not found but is postulated to be an unusually virulent infectious agent or aggressive host immune response. Common identifiable causes of ALF are shown in Table 22–8.

**Table 22–8.** Common identifiable causesa of acute liver failure by age.

<table>
<thead>
<tr>
<th>Age</th>
<th>Causes</th>
</tr>
</thead>
</table>

AIH, autoimmune hepatitis; EBV, Epstein-Barr virus; FAO, fatty acid oxidation defects; HAV, hepatitis A; HBV, hepatitis B; HLH, hemophagocytic lymphohistiocytosis.
aUnknown cause of ALF remains the most common etiology.

**Clinical Findings**

**A. History**

In some patients, ALF presents with the rapid development of deepening jaundice, bleeding, confusion, and progressive coma, while others are asymptomatic at the onset and then suddenly become severely ill during the second week of the disease. Jaundice, fever, anorexia, vomiting, and abdominal pain are the most common symptoms. A careful history of drug and toxin exposure may identify a drug-induced cause.

**B. Symptoms and Signs**

Children may present with flu-like symptoms, including malaise, myalgias, jaundice, nausea, and vomiting. Tender hepatomegaly is common, which may be followed by progressive shrinking of the liver, often with worsening hepatic function. Other physical findings (splenomegaly, spider hemangiomata) should suggest an underlying chronic liver disease. Hyper-reflexia and positive extensor plantar responses are seen before the onset of encephalopathy.

**C. Laboratory Findings**

Characteristic findings include elevated serum bilirubin levels (usually > 15–20 mg/dL), sustained elevations of AST and ALT (> 3000 U/L), low serum albumin, hypoglycemia, and prolonged PT and INR. Blood ammonia levels become elevated, whereas blood urea nitrogen is often very low. Prolonged PT from disseminated intravascular coagulation (DIC) can be differentiated by determination of factor V (low in ALF and DIC) and VIII (normal to high in ALF and low in DIC). Rapid decreases in AST and ALT, together with shrinking hepatomegaly, due to massive necrosis and collapse, combined with worsening coagulopathy portend a poor prognosis. A high AST and ALT with normal bilirubin suggests acetaminophen toxicity or metabolic causes.

**Differential Diagnosis**

Severe hepatitis, with or without coagulopathy, due to infections, metabolic disease, autoimmune hepatitis or drug toxicity can initially mimic ALF. Acute leukemia, cardiomyopathy, and Budd-Chiari syndrome can mimic severe hepatitis. Patients with Reye syndrome or urea cycle defects are typically anicteric.

**Complications**

The development of renal failure and depth of hepatic coma are major prognostic factors. Patients in stage 4 coma (unresponsiveness to verbal stimuli, decorticate or decerebrate posturing) rarely survive without liver transplantation and may have residual central nervous system deficits even after transplant. Cerebral edema, which usually accompanies coma, is frequently the cause of death. Extreme prolongation
of PT or INR greater than 3.5 predicts poor recovery, except with acetaminophen overdose. Sepsis, hemorrhage, renal failure, and cardiorespiratory arrest are common terminal events.

**Treatment**

Excellent critical care is paramount, including careful management of hypoglycemia, bleeding and coagulopathy, hyperammonemia, cerebral edema, and fluid balance, while systematically investigating for potentially treatable causes. Several therapies have failed to affect outcome, including exchange transfusion, plasmapheresis with plasma exchange, total body washout, charcoal hemoperfusion, and hemodialysis using a special high-permeability membrane. While spontaneous survival may occur in up to 50% of patients, liver transplant may be lifesaving in patients without signs of spontaneous recovery. Therefore, early transfer of patients in ALF to centers where liver transplantation can be performed is recommended. Criteria for deciding when to perform transplantation are not firmly established; serum bilirubin over 20 mg/dL, INR greater than 4, and factor V levels less than 20% indicate a poor prognosis. Prognosis is better for acetaminophen ingestion, particularly when N-acetylcysteine treatment is given. N-acetylcysteine is not recommended in non-acetaminophen induced liver failure, as it does not improve survival and may, in fact, negatively impact survival in those younger than 2 years. Corticosteroids may be harmful, except in autoimmune hepatitis for which steroids may reverse ALF. Acyclovir is essential in herpes simplex or varicella-zoster virus infection. For hyperammonemia, oral antibiotics such as neomycin or rifaximin, and lactulose (1–2 mL/kg three or four times daily) are used to reduce blood ammonia levels and trap ammonia in the colon. Close monitoring of fluid and electrolytes is mandatory and requires a central venous line. Adequate dextrose should be infused (6–8 mg/kg/min) to maintain normal blood glucose and cellular metabolism. Diuretics, sedatives, and tranquilizers should be used sparingly. Early signs of cerebral edema are treated with infusions of mannitol (0.5–1.0 g/kg). Comatose patients should be intubated, given mechanical ventilatory support, and monitored for signs of infection. Coagulopathy is treated with fresh-frozen plasma, recombinant factor VIIa, other clotting factor concentrates, platelet infusions, or exchange transfusion for bleeding or procedures. Hemodialysis may help stabilize a patient while awaiting liver transplantation. Monitoring for increased intracranial pressure (hepatic coma stages 3 and 4) in patients awaiting liver transplantation is advocated by some. Continuous venous-venous dialysis may be helpful to maintain fluid balance.

**Prognosis**

Prognosis is primarily dependent on the etiology of ALF and depth of coma. Only 20%–30% of children with stage 3 or 4 hepatic encephalopathy will have a spontaneous recovery. Children with acute acetaminophen toxicity have a high rate of spontaneous survival, while 40% of children with indeterminate ALF (of unknown etiology) will have a spontaneous recovery. A recent large study suggests that the spontaneous recovery rate is about 40%–50% when all causes of ALF are combined; 30% of patients will receive a liver transplant; and 20% will die without a transplant. Exchange transfusions or other modes of heroic therapy do not improve survival figures. Indeterminate ALF, non-acetaminophen drug-induced ALF, and ALF in infants are associated with a poorer prognosis. Acetaminophen and autoimmune hepatitis etiologies of ALF and rising levels of factors V and VII, coupled with rising levels of serum α-fetoprotein, may signify a more favorable prognosis. The 1-year survival rate in patients who undergo liver transplantation for ALF is 60%–85%.

**Autoimmune Hepatitis**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Acute or chronic hepatitis.
- Hypergammaglobulinemia.
- Positive antinuclear antibodies (ANA), anti–smooth muscle (or actin) antibodies (ASMA), anti–liver-kidney microsomal (LKM) antibodies, or anti–soluble liver antigen antibodies (SLA).

**Clinical Findings**

**A. History**

Autoimmune hepatitis (AIH) is a progressive inflammatory disorder. It is characterized histologically by portal tract inflammation that extends into the parenchyma; serologically by the presence of nonorgan-specific autoantibodies; biochemically by elevated aminotransferases and serum IgG;
and clinically by response to immunosuppressive treatment in the absence of other known causes of liver disease. A family history of autoimmune diseases is present in approximately 40% of cases.

B. Symptoms and Signs

Pediatric patients are often asymptomatic early in the disease process and come to medical attention based on an incidental finding of elevated liver tests. Lethargy as well as malaise is a common symptom, and patients may also complain of jaundice, recurrent fevers, abdominal pain, or distension. Other complaints at the time of presentation may include a recurrent rash, arthritis, chronic diarrhea, or amenorrhea. Hepatomegaly and/or splenomegaly may be found on examination, in association with elevated liver tests. In more advanced cases, jaundice and ascites may develop. Cutaneous signs of chronic liver disease may be noted (eg, spider angiomas, palmar erythema, and digital clubbing). In ~10% of cases, AIH patients present with acute liver failure (ALF).

C. Laboratory Findings

Liver tests reveal moderate elevations of serum AST, ALT, and variable elevations of alkaline phosphatase, bilirubin, and total IgG. Two subtypes of disease have been described based on the autoantibodies present: type 1 AIH—ANA and/or ASMA (anti-actin); type 2 AIH—anti-LKM (anti-liver kidney microsomal). Type 1 AIH is the most common form of AIH in the United States. Type 2 AIH is more common in Europe, presents at a younger age and is more likely to present with ALF compared to type 1. A genetic susceptibility to AIH is suggested by the increased incidence of the histocompatibility alleles HLA DR*0301 (type 1 AIH) or HLA DR*0701 (type 2 AIH). Liver biopsy remains the gold standard in diagnosis, revealing the typical histological picture of interface hepatitis: a dense infiltration of the portal tracts consisting mainly of lymphocytes and plasma cells that extends into the liver lobules with destruction of the hepatocytes at the periphery of the lobule and erosion of the limiting plate. There may be bridging fibrosis or cirrhosis evident as well.

Differential Diagnosis

Laboratory and histologic findings differentiate other types of chronic hepatitis (eg, HBV, HCV; steatohepatitis; Wilson disease; α₁-antitrypsin deficiency; primary sclerosing cholangitis [PSC]). PSC occasionally presents in a manner similar to AIH, including the presence of autoantibodies. Up to 30% of pediatric patients have an “overlap syndrome” of AIH and PSC. Drug-induced chronic hepatitis (minocycline, isoniazid, methyldopa, pemoline) should be ruled out. In addition, minocycline has been reported as a potential “trigger” of type 1 AIH.

Complications

Untreated disease that continues for months to years eventually results in cirrhosis, with complications of portal hypertension and liver synthetic dysfunction. Persistent malaise, fatigue, amenorrhea, and anorexia parallel disease activity. Bleeding from esophageal varices and development of ascites usually signal impending hepatic failure.

Treatment

Corticosteroids (prednisone, 2 mg/kg/day; maximum 60 mg) as induction therapy decreases the mortality rate during the early active phase of the disease. Recent data suggests that oral budesonide may be as efficacious as prednisone at inducing remission with less steroid side effects. Budesonide is not as potent an anti-inflammatory as prednisone and studies suggest that budesonide should be reserved for mild cases at presentation (ie, mild elevation of liver transaminases and minimal/ no fibrosis on liver histology). Maintenance therapy with azathioprine or 6-mercaptopurine (6-MP), 1–2 mg/kg/day, is recommended in order facilitate weaning off of steroids. Thiopurine methyltransferase activity in red blood cells or genotype should be assessed prior to starting azathioprine or 6-MP, to prevent extremely high blood levels and severe bone marrow toxicity. Steroids are reduced over a 3- to 6-month period, and azathioprine is continued for at least 2 years. At that point, if AST and ALT have been consistently normal in type 1 AIH, then one can consider a future wean off of therapy. A liver biopsy must be performed before stopping azathioprine or 6-MP therapy; if any inflammation persists, then azathioprine or 6-MP is continued. The majority of pediatric patients will require chronic azathioprine or 6-MP therapy, but up to 30% can be taken off of azathioprine or 6-MP eventually. Relapses are treated with a course of steroids. Type 2 AIH patients must remain on azathioprine and low dose corticosteroids. Cyclosporine, tacrolimus, or methotrexate may be helpful in poorly responsive cases. Mycophenolate mofetil can be substituted for azathioprine or 6-MP if there is a contraindication or side effect from these medications. Liver transplantation is indicated when disease progresses to decompensated cirrhosis or in cases presenting in ALF that do not respond to steroid therapy.

Prognosis

The overall prognosis for AIH has improved significantly with early therapy; approximately 90% of patients with type 1 AIH will enter remission. Some studies report permanent remission (normal histologic findings) in up to 20% of patients. Relapses (seen clinically and histologically) occur in 40%–50% of patients after cessation of therapy; remissions follow repeat treatment. Complications of portal hypertension (bleeding varices, ascites, spontaneous bacterial peritonitis, and hepatopulmonary syndrome) require
specific therapy or liver transplant. Disease recurs after transplantation in ~ 20% of cases and is treated by adding azathioprine or mycophenolate mofetil to the post-transplant immunosuppressant regimen.

NONALCOHOLIC FATTY LIVER DISEASE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Hepatomegaly in patient with BMI more than 95th percentile.
- Elevated ALT > AST.
- Detection of fatty infiltration of the liver on ultrasound.
- Histologic evidence of fat in the liver.
- Insulin resistance.

Nonalcoholic fatty liver disease (NAFLD), a clinicopathologic condition of abnormal hepatic fat deposition in the absence of alcohol, is the most common cause of abnormal liver function tests in the United States. NAFLD ranges from bland steatosis, to fat and inflammation, with or without scarring (also referred to as nonalcoholic steatohepatitis, NASH) to cirrhosis. Trends in NAFLD parallel trends in obesity, with up to 10% of all children, and 38% of obese children affected in the United States. Many children with NAFLD are also affected by type 2 diabetes mellitus, hypertension, hyperlipidemia, and the metabolic syndrome. Most children are 11–13 years of age at diagnosis, with males (ratio of 2:1) and Hispanics at highest risk.

Prevention

The most effective therapy is prevention of the overweight or obese state.

Clinical Findings

A. History

Most patients with NAFLD are asymptomatic and discovered upon routine screening. Some may complain of fatigue or right upper quadrant pain. Obesity and insulin resistance are known risk factors. Moderate sleep apnea is also common in children with NAFLD.

B. Symptoms and Signs

Patients with NAFLD may present with asymptomatic soft hepatomegaly, though abdominal adiposity may make this difficult to assess. Physical findings of insulin resistance (acanthosis nigricans and a buffalo hump) are frequently present.

C. Laboratory Findings

Serum aminotransferases will not identify bland steatosis, so NAFLD patients may have completely normal AST and ALT. If elevated, the AST and ALT are typically elevated less than 1.5 times the upper limit of normal, with an ALT:AST ratio of > 1. Alkaline phosphatase and GGT may be mildly elevated, but bilirubin is normal. Hyperglycemia and hyperlipidemia are also common. If performed, the liver biopsy may show micro- or macrovesicular steatosis, hepatocyte ballooning, Mallory bodies, and lobular or portal inflammation. In addition, varying degrees of fibrosis from portal focused to cirrhosis may be present. Obstructive sleep apnea and hypoxia appear to contribute to NAFLD disease severity. There are no established reliable biochemical predictors of the degree of hepatic fibrosis, but new biomarkers, like patatin-like phospholipase domain-containing three polymorphisms and cytokeratin-18, show promise in research laboratories.

D. Imaging

Ultrasonography, CT scan, or MRI can be used to confirm fatty infiltration of the liver. Ultrasound, however, is of lower cost and lacks radiation exposure, although it may be insensitive with severe central adiposity or if less than 30% steatosis is present. Currently, radiologic imaging cannot distinguish bland steatosis from the more severe NASH, nor reliably identify fibrosis. Transient elastography and MR elastography are increasingly available as clinical tools that shows promise in accurately estimating both hepatic fat and fibrosis.

Differential Diagnosis

Steatohepatitis is also associated with Wilson disease, hereditary fructose intolerance, tyrosinemia, HCV hepatitis, cystic fibrosis, fatty acid oxidation defects, kwashiorkor, Reye syndrome, respiratory chain defects, total parenteral nutrition associated liver disease, and toxic hepatopathy (ethanol and others).

Complications

Untreated, NAFLD with hepatic inflammation can progress to cirrhosis with complications that include portal hypertension. Dyslipidemia, hypertension, insulin resistance and obstructive sleep apnea are more common in children and adolescents with NAFLD.
Treatment

Multiple potential therapies, including metformin, UDCA, and lipid-lowering agents have been tested without therapeutic success. Therefore, treatment is focused on lifestyle modifications, through both dietary changes and exercise, to induce slow weight loss. A 10% decrease in body weight can significantly improve NAFLD. Vitamin E, an antioxidant, has shown promise in clinical trials in improving histologically confirmed NASH.

Prognosis

Although untreated NAFLD can progress to cirrhosis and liver failure; there is a very high response rate to weight reduction. However, success in achieving long-term weight reduction is low in children and adults.

α₁-ANTITRYPSIN DEFICIENCY LIVER DISEASE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Serum α₁-antitrypsin level < 50–80 mg/dL.
- Identification of a specific protease inhibitor (PI) phenotype (PIZZ, PISZ) or genotype.
- Detection of diastase-resistant glycoprotein deposits in periportal hepatocytes.
- Histologic evidence of liver disease.
- Family history of early-onset pulmonary disease or liver disease.

General Considerations

The disease is caused by a deficiency in α₁-antitrypsin, a protease inhibitor (Pi) system, predisposing patients to chronic liver disease, and an early onset of pulmonary emphysema. Liver disease is associated only with the Pi phenotypes ZZ and SZ. The accumulation of misfolded aggregates of α₁-antitrypsin protein in the liver causes the liver injury by unclear mechanisms.

Clinical Findings

A. Symptoms and Signs

α₁-Antitrypsin deficiency should be considered in all infants with neonatal cholestasis. About 10%–20% of affected individuals present with neonatal cholestasis. Serum GGT is usually elevated, jaundice, acholic stools, and malabsorption may also be present. Infants are often small for gestational age, and hepatosplenomegaly may be present. The family history may be positive for emphysema or cirrhosis.

The disease can also present in older children, where hepatomegaly or physical findings suggestive of cirrhosis and portal hypertension should lead to consideration of α₁-antitrypsin deficiency. Recurrent pulmonary disease (bronchitis, pneumonia) may be present in some older children. Very few children have significant pulmonary involvement. Most affected children are completely asymptomatic, with no laboratory or clinical evidence of liver or lung disease.

B. Laboratory Findings

Serum α₁-Antitrypsin level is low (< 50–80 mg/dL) in homozygotes (PiZZ). Specific Pi phenotyping or genotyping should be done to confirm the diagnosis. LFTs often reflect underlying hepatic pathologic changes. Hyperbilirubinemia (mixed) and elevated aminotransferases, alkaline phosphatase, and GGT are present early. Hyperbilirubinemia generally resolves, while aminotransferase and GGT elevation may persist. Signs of cirrhosis and hypersplenism may develop even when LFTs are normal.

Liver biopsy findings after age 6 months show diastase resistant, periodic acid–Schiff staining intracellular globules, particularly in perportal zones. These may be absent prior to age 6 months, but when present are characteristic of α₁-antitrypsin deficiency.

Differential Diagnosis

In newborns, other specific causes of neonatal cholestasis need to be considered, including biliary atresia. In older children, other causes of insidious cirrhosis (eg, HBV or HCV infection, AIH, Wilson disease, cystic fibrosis, and glycogen storage disease) should be considered.

Complications

Of all infants with PiZZ α₁-antitrypsin deficiency, only 15%–20% develop liver disease in childhood, and many have clinical recovery. Thus, other genetic or environmental...
modifiers must be involved. An associated abnormality in the microsomal disposal of accumulated aggregates may contribute to the liver disease phenotype. The complications of portal hypertension, cirrhosis, and chronic cholestasis predominate in affected children. Occasionally, children develop paucity of interlobular bile ducts.

Early-onset pulmonary emphysema occurs in young adults (age 30–40 years), particularly in smokers. An increased susceptibility to hepatocellular carcinoma has been noted in cirrhosis associated with α1-antitrypsin deficiency.

**Treatment**

There is no specific treatment for the liver disease of this disorder. Replacement of the protein by infusion therapy is used to prevent or treat pulmonary disease in affected adults. The neonatal cholestatic condition is treated with choleretics, medium-chain triglyceride–containing formula, and water-soluble preparations of fat-soluble vitamins (see Table 22–4). UDCA may reduce AST, ALT, and GGT, but its effect on outcome is unknown. Clinical trials of carbamazepine are underway and other therapies are in development. Portal hypertension, esophageal bleeding, ascites, and other complications are treated as described elsewhere. Hepatitis A and B vaccines should be given to children with α1-antitrypsin deficiency. Genetic counseling is indicated when the diagnosis is made. Diagnosis by prenatal screening is possible. Liver transplantation, performed for end-stage liver disease cures the deficiency with excellent long-term survival and prevents the development of pulmonary disease. Passive and active cigarette smoke exposure should be eliminated to help prevent pulmonary manifestations, and obesity should be avoided.

**Prognosis**

Of those patients presenting with neonatal cholestasis, approximately 10%–25% will need liver transplantation in the first 5 years of life, 15%–25% during childhood or adolescence, and 50%–75% will survive into adulthood with variable degrees of liver fibrosis. A correlation between histologic patterns and clinical course has been documented in the infantile form of the disease. Liver failure can be expected 5–15 years after development of cirrhosis. Recurrence or persistence of hyperbilirubinemia along with worsening coagulation studies indicates the need for evaluation for liver transplantation. Decompensated cirrhosis caused by this disease is an indication for liver transplantation. Pulmonary involvement is prevented by liver transplantation. Heterozygotes may have a slightly higher incidence of liver disease. The exact relationship between low levels of serum α1-antitrypsin and the development of liver disease is unclear. Emphysema develops because of a lack of inhibition of neutrophil elastase, which destroys pulmonary connective tissue.

**Wilson Disease (Hepatolenticular Degeneration)**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Acute or chronic liver disease.
- Deteriorating neurologic status.
- Kayser-Fleischer rings.
- Elevated liver copper.
- Abnormalities in levels of ceruloplasmin and serum and urine copper.

**General Considerations**

Wilson disease is caused by mutations in the gene ATP7B on chromosome 13 coding for a specific P-type adenosine triphosphatase involved in copper transport. Thisresults in impaired bile excretion of copper and incorporation of copper into ceruloplasmin by the liver. The accumulated hepatic copper causes oxidant (free-radical) damage to the liver. Subsequently, copper accumulates in the basal ganglia and other tissues. The disease should be considered in all children older than age 2 years with evidence of liver disease (especially with hemolysis) or with suggestive neurologic signs. A family history is often present, and 25% of patients are identified by screening asymptomatic homozygous family members. The disease is autosomal recessive and occurs in 1:30,000 live births in all populations.

**Clinical Findings**

**A. Symptoms and Signs**

Hepatic involvement may present as acute liver failure, acute hepatitis, chronic liver disease, cholelithiasis, fatty liver disease, or as cirrhosis with portal hypertension. Findings may include jaundice, hepatomegaly early in childhood, splenomegaly, and Kayser-Fleischer rings. The disease is generally considered after 3–4 years of age. However, liver involvement occurs early in life and be present by age 2 years. The later onset of neurologic or psychiatric manifestations after age 10 years may include tremor, dysarthria, and drooling. Deterioration in school performance can be the earliest...
neurologic expression of disease. The Kayser-Fleischer ring is a brown band at the junction of the iris and cornea, generally requiring slit-lamp examination for detection. Absence of Kayser-Fleischer rings does not exclude this diagnosis.

B. Laboratory Findings

The laboratory diagnosis can be challenging. Plasma ceruloplasmin levels are usually less than 20 mg/dL. (Normal values are 23–43 mg/dL.) Low values, however, occur normally in infants younger than 3 months, and in at least 10%–20% of homozygotes the levels may be within the lower end of the normal range (20–30 mg/dL), particularly since immunnoassays are commonly used to measure ceruloplasmin. Rare patients with higher ceruloplasmin levels have been reported. Serum copper levels are low, but the overlap with normal is too great for satisfactory discrimination. In acute fulminant Wilson disease, serum copper levels are elevated markedly, owing to hepatic necrosis and release of copper. The presence of anemia, hemolysis, very high serum bilirubin levels (> 20–30 mg/dL), low alkaline phosphatase, and low uric acid are characteristic of acute Wilson disease. Urine copper excretion in children older than 3 years is normally less than 30 mcg/day; in Wilson disease, it is generally greater than 100 mcg/day although it can be as low as > 40 mcg/day. Finally, the tissue content of copper from a liver biopsy, normally less than 40–50 mcg/g dry tissue, is greater than 250 mcg/g in most Wilson disease patients, but may be as low as > 75 mcg/day.

Glycosuria and aminoaciduria have been reported. Hemolysis and gallstones may be present; bone lesions simulating those of osteochondritis dissecans have also been found.

The coarse nodular cirrhosis, macrovesicular steatosis, and glycogenated nuclei in hepatocytes seen on liver biopsy may distinguish Wilson disease from other types of cirrhosis. Early in the disease, vacuolation of liver cells, steatosis, and lipofuscin granules can be seen, as well as Mallory bodies. The presence of Mallory bodies in a child is strongly suggestive of Wilson disease. Stains for copper may sometimes be negative despite high copper content in the liver. Therefore, quantitative liver copper levels must be determined biochemically on biopsy specimens. Electron microscopy findings of abnormal mitochondria may be helpful.

■ Differential Diagnosis

During the icteric phase, acute or chronic viral hepatitis, α1-antitrypsin deficiency, autoimmune hepatitis, and drug-induced hepatitis are the usual diagnostic possibilities. Nonalcoholic steatohepatitis may have similar histology and be confused with Wilson disease in overweight patients. Later, other causes of cirrhosis and portal hypertension require consideration. Laboratory testing for plasma ceruloplasmin, 24-hour urine copper excretion, liver quantitative copper concentration, and a slit-lamp examination of the cornea will help differentiate Wilson disease from the others. Urinary copper excretion during penicillamine challenge (500 mg twice a day in the older child or adult) may also be helpful. Genetic testing of ATP7B is available and may be helpful if two disease-causing mutations are present. Other copper storage diseases that occur in early childhood include Indian childhood cirrhosis, Tyrolean childhood cirrhosis, and idiopathic copper toxicosis. However, ceruloplasmin concentrations are normal to elevated in these conditions.

■ Complications

Cirrhosis, hepatic coma, progressive neurologic degeneration, and death are the rule in the untreated patient. The complications of portal hypertension (variceal hemorrhage, ascites) may be present at diagnosis. Progressive central nervous system disease and terminal aspiration pneumonia were common in untreated older people. Acute hemolytic disease may result in acute renal failure and profound jaundice and coma as part of the presentation of fulminant hepatitis.

■ Treatment

Copper chelation with D-penicillamine or trientine hydrochloride, 750–1500 mg/day orally, is the treatment of choice, whether or not the patient is symptomatic. The target dose for children is 20 mg/kg/day; begin with 250 mg/day and increase the dose weekly by 250 mg increments. Strict dietary restriction of copper intake is not practical; however, selected high copper foods should be minimized. Supplementation with zinc acetate (25–50 mg orally, three times daily) may reduce copper absorption but must not be given at the same time as copper chelators. Copper chelation or zinc therapy is continued for life, although doses of chelators may be reduced transiently at the time of surgery or early in pregnancy. Vitamin B6 (25 mg) is given daily during therapy with penicillamine or trientine, zinc therapy is substituted and continued for life. Tetramethylpyridine is being tested as an alternative therapy. Noncompliance with any of the drug regimens (including zinc therapy) can lead to sudden fulminant liver failure and death.

Liver transplantation is indicated for all cases of acute fulminant disease (with hemolysis and renal failure), for progressive hepatic decompensation despite several months of therapy, and for severe progressive hepatic insufficiency in patients who inadvertently discontinue penicillamine, trientine, or zinc therapy.

■ Prognosis

The prognosis of untreated Wilson disease is poor. The fulminant presentation is fatal without liver transplantation in almost all cases. Copper chelation reduces hepatic copper content, reverses many of the liver lesions, and can stabilize
the clinical course of established cirrhosis. Neurologic symptoms generally respond to therapy. All siblings should be immediately screened and homozygotes given treatment with copper chelation or zinc acetate therapy, even if asymptomatic. Recent data suggest that zinc monotherapy may not be as effective for hepatic Wilson disease as copper chelation. Genetic testing (haplotype analysis or \( \text{ATP7B} \) genotyping) is available clinically if there is any doubt about the diagnosis and is particularly useful for screening family members.

**DRUG-INDUCED LIVER DISEASE**

**General Considerations**

Drug-induced liver injury (DILI) may be predictable or unpredictable. Predictable hepatotoxins cause liver injury in a dose-dependent manner. Unpredictable hepatotoxins cause liver injury in an idiosyncratic manner, which may be influenced by the genetic and environmental characteristics of particular individuals. DILI has been described with a wide variety of medications, including antihypertensives, acetaminophen, anabolic steroids, antibiotics, anticonvulsants, antidepressants, antituberculosis medications, antipsychotics, antivirals, herbs, dietary supplements, and weight loss agents.

**Symptoms**

Many people with DILI are asymptomatic and only detected because aminotransferases are performed for other reasons. If symptomatic, indicating more severe DILI, patients may have malaise, anorexia, nausea and vomiting, right upper quadrant pain, jaundice, acholic stools, and dark urine. Some may have severe pruritus. If the DILI is a hypersensitivity reaction, fever and rash may also occur.

**Diagnosis**

No specific testing for DILI is available, with diagnosis requiring a causality assessment. This assessment should determine if the patient was exposed to the drug during a logical time period; if the drug has previously been reported to cause DILI; and if the symptom complex is consistent with DILI. In addition, other explanations for liver injury should be sought, including viral hepatitis, autoimmune hepatitis, and alcohol use.

**Treatment**

Primary therapy is discontinuation of the offending drug, and avoiding reexposure. This typically results in rapid and complete resolution of symptoms. However, DILI severe enough to cause acute liver failure has a poor prognosis without urgent liver transplant. Specific therapies for some DILI etiologies include N-acetylcysteine for acetaminophen poisoning. The use of ursodeoxycholic acid may speed resolution of jaundice. The use of corticosteroids for DILI remains controversial. An NIH sponsored website provides up-to-date information about each drug and herbal substance associated with DILI (Liver Tox).

**CIRRHOSIS**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Underlying liver disease.
- Nodular hard liver and splenomegaly.
- Nodular liver on abdominal imaging.
- Liver biopsy demonstrating cirrhosis.

**General Considerations**

Cirrhosis is a histologically defined condition of the liver characterized by diffuse hepatocyte injury and regeneration, an increase in connective tissue (bridging fibrosis), and disorganization of the lobular and vascular architecture (regenerative nodules). It may be micronodular or macronodular in appearance. It is the vasculature distortion that leads to increased resistance to blood flow, producing portal hypertension, and its consequences.

Many liver diseases may progress to cirrhosis. In children, the two most common forms of cirrhosis are postnecrotic and biliary, each of which has different causes, symptoms, and treatments. Both forms can eventually lead to liver failure and death.
Clinical Findings

A. History
Many children with cirrhosis may be asymptomatic early in the course. Malaise, loss of appetite, failure to thrive, and nausea are frequent complaints, especially in anicteric varieties. Easy bruising may be reported. Jaundice may or may not be present.

B. Symptoms and Signs
The first indication of underlying liver disease may be splenomegaly, ascites, gastrointestinal hemorrhage, or hepatic encephalopathy. Variable hepatomegaly, spider angiomas, warm skin, palmar erythema, or digital clubbing may be present. A small, shrunken liver may present. Most often, the liver is enlarged slightly, especially in the subxiphoid region, where it has a firm to hard quality and an irregular edge. Splenomegaly generally precedes other complications of portal hypertension. Ascites, gynecomastia in males, digital clubbing, pretibial edema, and irregularities of menstruation in females may be present. In biliary cirrhosis, patients often also have jaundice, dark urine, pruritus, hepatomegaly, and sometimes xanthomas. Malnutrition and failure to thrive due to steatorrhea may be more apparent in this form of cirrhosis.

C. Laboratory Findings
Mild abnormalities of AST and ALT are often present, with a decreased level of albumin. PT is prolonged and may be unresponsive to vitamin K administration. Burr and target red cells may be noted on the peripheral blood smear. Anemia, thrombocytopenia, and leukopenia are present if hypersplenism exists. However, blood tests may be normal in patients with cirrhosis. In biliary cirrhosis, increased levels of conjugated bilirubin, bile acids, GGT, alkaline phosphatase, and cholesterol are common.

D. Imaging
Hepatic ultrasound, CT, or MRI examination may demonstrate abnormal hepatic texture and nodules. In biliary cirrhosis, abnormalities of the biliary tree may be apparent. Elastography will demonstrate increased liver stiffness.

E. Pathologic Findings
Liver biopsy findings of regenerating nodules and surrounding fibrosis are hallmarks of cirrhosis. Pathologic features of biliary cirrhosis also include canalicular and hepatocyte cholestasis, as well as plugging of bile ducts. The interlobular bile ducts may be increased or decreased, depending on the cause and the stage of the disease process.

Differential Diagnosis
In the pediatric population, postnecrotic cirrhosis is often a result of acute or chronic liver disease (eg, viral hepatitis [HBV, HCV], autoimmune, α1 antitrypsin deficiency, Wilson disease or drug-induced liver injury), more recently NAFLD, or certain inborn errors of metabolism (see Table 22–5). The evolution to cirrhosis may be insidious, with no recognized icteric phase. At the time of diagnosis of cirrhosis, the underlying liver disease may be active, with abnormal LFTs; or it may be quiescent, with normal LFTs. Most cases of biliary cirrhosis result from congenital abnormalities of the bile ducts (biliary atresia, choledochal cyst), tumors of the bile duct, Caroli disease, progressive familial intrahepatic cholangitis, primary sclerosing cholangitis, paucity of the intrahepatic bile ducts, and cystic fibrosis. Parasites (Opisthorchis sinensis, Fasciola, Schistosoma, and Ascaris) may be causative in children living in endemic areas.

Complications
Major complications of cirrhosis in childhood include progressive nutritional disturbances, hormonal disturbances, and the evolution of portal hypertension and its complications. Hepatocellular carcinoma occurs with increased frequency in the cirrhotic liver, especially in patients with the chronic form of hereditary tyrosinemia or after long-standing HBV or HCV disease.

Treatment
At present, there is no proven medical treatment for cirrhosis, but whenever a treatable condition is identified (eg, Wilson disease, galactosemia, autoimmune hepatitis) or an offending agent eliminated (HBV, HCV, drugs, toxins), disease progression can be altered; occasionally regression of fibrosis has been noted. Recent evidence suggests that cirrhosis from HCV and HBV may be reversed by successful antiviral therapy. Children with cirrhosis should receive the hepatitis A and B vaccines and be monitored for the development of hepatocellular carcinoma with serial serum α-fetoprotein determinations annually and abdominal ultrasound for hepatic nodules at least annually. Liver transplantation may be appropriate in patients with: cirrhosis caused by a progressive disease; evidence of worsening hepatic synthetic function; or complications of cirrhosis that are no longer manageable.

Prognosis
Cirrhosis has an unpredictable course. Without transplantation, affected patients may die from liver failure within 10–15 years. Patients with a rising bilirubin, a vitamin K–resistant coagulopathy, or diuretic refractory ascites usually survive less than 1–2 years. The terminal event in some
patients may be generalized hemorrhage, sepsis, or cardiorespiratory arrest. For patients with biliary cirrhosis, the prognosis is similar, except for those with surgically corrected lesions that result in regression or stabilization of the underlying liver condition. With liver transplantation, the long-term survival rate is 70%–90%.

PORTAL HYPERTENSION

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► Splenomegaly.
► Recurrent ascites.
► Variceal hemorrhage.
► Hypersplenism.

General Considerations

Portal hypertension is defined as an increase in the portal venous pressure to more than 5 mm Hg greater than the inferior vena caval pressure. Portal hypertension is most commonly a result of cirrhosis. Portal hypertension may be divided into prehepatic, suprahepatic, and intrahepatic causes. Although the specific lesions vary somewhat in their clinical signs and symptoms, the consequences of portal hypertension are common to all.

A. Prehepatic Portal Hypertension

Prehepatic portal hypertension from acquired abnormalities of the portal and splenic veins accounts for 30%–50% of cases of variceal hemorrhage in children. A history of neonatal omphalitis, sepsis, dehydration, or umbilical vein catheterization may be present. Causes in older children include local trauma, peritonitis (pyelophlebitis), hypercoagulable states, and pancreatitis. Symptoms may occur before age 1 year, but in most cases the diagnosis is not made until age 3–5 years. Patients with a positive neonatal history tend to be symptomatic earlier.

A variety of portal or splenic vein malformations, some of which may be congenital, have been described, including defects in valves and atretic segments. Cavernous transformation is the result of attempted collateralization around the thrombosed portal vein rather than a congenital malformation. The site of the venous obstruction may be anywhere from the hilum of the liver to the hilum of the spleen.

B. Suprahepatic Vein Occlusion or Thrombosis (Budd-Chiari Syndrome)

No cause can be demonstrated in most instances in children, while tumor, medications, and hypercoagulable states are common causes in adults. The occasional association of hepatic vein thrombosis in inflammatory bowel disease favors the presence of endogenous toxins traversing the liver. Vasculitis leading to endophlebitis of the hepatic veins has been described. In addition, hepatic vein obstruction may be secondary to tumor, abdominal trauma, hyperthermia, or sepsis, or it may occur following the repair of an omphalocele or gastroschisis. Congenital vena caval bands, webs, a membrane, or stricture above the hepatic veins are sometimes causative. Hepatic vein thrombosis may be a complication of oral contraceptive medications. Underlying thrombotic conditions (deficiency of antithrombin III, protein C or S, or factor V Leiden; antiphospholipid antibodies; or mutations of the prothrombin gene) are common in adults.

C. Intrahepatic Portal Hypertension

1. Cirrhosis—See previous section.

2. Veno-occlusive disease (acute stage)—This entity occurs most frequently in bone marrow or stem cell transplant recipients. Additional causes include high-dose thiopurines, ingestion of pyrrolizidine alkaloids (“bush tea”) or other herbal teas, and a familial form of the disease occurring in congenital immunodeficiency states. The acute form of the disease generally occurs in the first month after bone marrow transplantation and is heralded by the triad of weight gain (ascites), tender hepatomegaly, and jaundice.

3. Congenital hepatic fibrosis—This is a rare autosomal recessive cause of intrahepatic presinusoidal portal hypertension (see Table 22–10). Liver biopsy is generally diagnostic, demonstrating Von Meyenburg complexes (abnormal clusters of ectatic bile ducts). On angiography, the intrahepatic branches of the portal vein may be duplicated. Autosomal recessive polycystic kidney disease is frequently associated with this disorder.

4. Other rare causes—Hepatoportal sclerosis (idiopathic portal hypertension, noncirrhotic portal fibrosis), focal nodular regeneration of the liver, and schistosomal hepatic fibrosis are also rare causes of intrahepatic presinusoidal portal hypertension.
Clinical Findings

A. Symptoms and Signs

For prehepatic portal hypertension, splenomegaly in an otherwise well child is the most common physical sign. Ascites may be noted. The usual presenting symptoms are hematemesis and melena.

The presence of prehepatic portal hypertension is suggested by: (1) an episode of severe infection in the newborn period or early infancy—especially omphalitis, sepsis, gastroenteritis, severe dehydration, or prolonged or difficult umbilical vein catheterizations; (2) no previous evidence of liver disease; (3) a history of well-being prior to onset or recognition of symptoms; and (4) normal liver size and liver tests with splenomegaly.

Most patients with suprahepatic portal hypertension present with abdominal pain, tender hepatomegaly of acute onset, and ascites. Jaundice is present in only 25% of patients. Vomiting, hematemesis, and diarrhea are less common. Cutaneous signs of chronic liver disease are often absent, as the obstruction is usually acute. Distended superficial veins on the back and the anterior abdomen, along with dependent edema, are seen when inferior vena cava obstruction affects hepatic vein outflow. Absence of hepatojugular reflux (jugular distention when pressure is applied to the liver) is a helpful clinical sign.

The symptoms and signs of intrahepatic portal hypertension are generally those of cirrhosis (see earlier section on Cirrhosis).

B. Laboratory Findings and Imaging

Most other common causes of splenomegaly or hepatosplenomegaly may be excluded by appropriate laboratory tests. Cultures, EBV and hepatitis serologies, blood smear examination, bone marrow studies, and LFTs may be necessary. In prehepatic portal hypertension, LFTs are generally normal. In Budd-Chiari syndrome and veno-occlusive disease, mild to moderate hyperbilirubinemia with modest elevations of AST, ALT, and PT/INR are often present. Significant early increases in fibrinolytic parameters (especially plasminogen activator inhibitor 1) have been reported in veno-occlusive disease. Hypersplenism with mild leukopenia and thrombocytopenia is often present. Upper endoscopy may reveal varices in symptomatic patients.

Doppler-assisted ultrasound scanning of the liver, portal vein, splenic vein, inferior vena cava, and hepatic veins may assist in defining the vascular anatomy. In prehepatic portal hypertension, abnormalities of the portal or splenic vein may be apparent, whereas the hepatic veins are normal. When noncirrhotic portal hypertension is suspected, angiography often is diagnostic. Selective arteriography of the superior mesenteric artery or MRI is recommended prior to surgical shunting to determine the patency of the superior mesenteric vein.

For suprahepatic portal hypertension, an inferior vena cavaogram using catheters from above or below the suspected obstruction may reveal an intrinsic filling defect, an infiltrating tumor, or extrinsic compression of the inferior vena cava by an adjacent lesion. A large caudate lobe of the liver suggests Budd-Chiari syndrome. Care must be taken in interpreting extrinsic pressure defects of the subdiaphragmatic inferior vena cava if ascites is significant.

Simultaneous wedged hepatic vein pressure and hepatic venography are useful to demonstrate obstruction to major hepatic vein ostia and smaller vessels. In the absence of obstruction, reflux across the sinusoids into the portal vein branches can be accomplished. Pressures should also be taken from the right heart and supradiaphragmatic portion of the inferior vena cava to eliminate constrictive pericarditis and pulmonary hypertension from the differential diagnosis.

Differential Diagnosis

All causes of splenomegaly must be included in the differential diagnosis. The most common ones are infections, immune thrombocytopenic purpura, blood dyscrasias, lipodisosis, reticuloendotheliosis, cirrhosis of the liver, and cysts or hemangiomas of the spleen. When hematemesis or melena occurs, other causes of gastrointestinal bleeding are possible, such as gastric or duodenal ulcers, tumors, duplications, and inflammatory bowel disease.

Because ascites is almost always present in suprahepatic portal hypertension, cirrhosis resulting from any cause must be excluded. Other suprahepatic (cardiac, pulmonary) causes of portal hypertension must also be ruled out. Although ascites may occur in prehepatic portal hypertension, it is uncommon.

Complications

The major manifestation and complication of portal hypertension is bleeding from esophageal varices. Fatal exsanguination is uncommon, but hypovolemic shock or resulting anemia may require prompt treatment. Hypersplenism with leukopenia and thrombocytopenia occurs, but seldom causes major symptoms.

Without treatment, complete and persistent hepatic vein obstruction in suprahepatic portal hypertension leads to liver failure, coma, and death. A nonportal type of cirrhosis may develop in the chronic form of hepatic veno-occlusive disease in which small- and medium-sized hepatic veins are affected. Death from renal failure may occur in rare cases of congenital hepatic fibrosis.
CHAPTER 22

Treatment

Definitive treatment of noncirrhotic portal hypertension is generally lacking. Aggressive medical treatment of the complications of prehepatic portal hypertension is generally quite effective. Excellent results with either portosystemic shunt or the mesorex (mesenterico–left portal bypass) shunt. When possible, the mesorex shunt is the preferred technique. Veno-occlusive disease may be prevented somewhat by the prophylactic use of UDCA or defibrotide prior to conditioning for bone marrow transplantation. Treatment with defibrotide and withdrawal of the suspected offending agent, if possible, may increase the chance of recovery. Transjugular intrahepatic portosystemic shunts have been successful in bridging to recovery in veno-occlusive disease. For suprahepatic portal hypertension, efforts should be directed at correcting the underlying cause, if possible. Either surgical or angiographic relief of obstruction should be attempted if a defined obstruction of the vessels is apparent. Liver transplantation, if not contraindicated, should be considered early if direct correction is not possible. In most cases, management of portal hypertension is directed at management of the complications (Table 22–9).

Prognosis

For prehepatic portal hypertension, the prognosis depends on the site of the block, the effectiveness of variceal eradication, the availability of suitable vessels for shunting procedures, and the experience of the surgeon. In patients treated by medical means, bleeding episodes seem to diminish with adolescence.

The prognosis in patients treated by medical and supportive therapy may be better than in the surgically treated group, especially when surgery is performed at an early age, although no comparative study has been done. Portacaval encephalopathy is unusual after shunting except when protein intake is excessive, but neurologic outcome may be better in patients who receive a mesorex shunt when compared with medical management alone.

The mortality rate of hepatic vein obstruction is very high (95%). In veno-occlusive disease, the prognosis is better, with complete recovery possible in 50% of acute forms and 5%–10% of subacute forms.

BILIARY TRACT DISEASE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

» Episodic right upper quadrant abdominal pain.
» Elevated bilirubin, alkaline phosphatase, and GGT.
» Stones or sludge seen on abdominal ultrasound.

1. Cholelithiasis

General Considerations

Gallstones may develop at all ages in the pediatric population and in utero. Gallstones may be divided into cholesterol stones (> 50% cholesterol) and pigment (black [sterile bile] and brown [infected bile]) stones. Pigment stones predominate in the first decade of life, while cholesterol stones account for up to 90% of gallstones in adolescence. For some patients, gallbladder dysfunction is associated with biliary sludge formation, which may evolve into gallstones. The process is reversible in many patients.

Clinical Findings

A. History

Most symptomatic gallstones are associated with acute or recurrent episodes of moderate to severe, sharp right upper quadrant, or epigastric pain. The pain may radiate substernally or to the right shoulder. On rare occasions, the presentation may include a history of jaundice, back pain, or generalized abdominal discomfort, when it is associated with pancreatitis, suggesting stone impaction in the common duct or ampulla hepatopancreatica. Nausea and vomiting may occur during attacks. Pain episodes often occur postprandially, especially after ingestion of fatty foods. The groups at risk for gallstones include patients with known or suspected hemolytic disease; females; teenagers with prior pregnancy; obese individuals; individuals with rapid weight loss; children with portal vein thrombosis; certain racial or ethnic groups, particularly Native Americans (Pima Indians) and Hispanics; infants and children with ileal disease (Crohn disease) or prior ileal resection; patients with cystic fibrosis or Wilson disease; infants on prolonged parenteral hyperalimentation and those with bile acid transporter defects. Other, less certain risk factors include a positive family history, use of birth control pills, and diabetes mellitus.

B. Symptoms and Signs

During acute episodes of pain, tenderness is present in the right upper quadrant or epigastrium, with a positive inspiratory arrest (Murphy sign), usually without peritoneal signs. While rarely present, scleral icterus is helpful. Evidence of underlying hemolytic disease in addition to icterus may include pallor (anemia), splenomegaly, tachycardia, and high-output cardiac murmur. Fever is unusual in uncomplicated cases.

C. Laboratory Findings

Laboratory tests are usually normal unless calculi have lodged in the extrahepatic biliary system, in which case the serum bilirubin and GGT (or alkaline phosphatase) may be elevated. Amylase and lipase levels may be increased if stone obstruction occurs at the ampulla hepatopancreatica.

D. Imaging

Ultrasound evaluation is the best imaging technique, showing abnormal intraluminal contents (stones, sludge) as well as anatomic alterations of the gallbladder or dilation of the biliary ductal system. The presence of an anechoic acoustic shadow differentiates calculi from intraluminal sludge or sludge balls. Lack of visualization of the gallbladder with hepatobiliary scintigraphy suggests chronic cholecystitis. In selected cases, ERCP, MRCP, or endoscopic ultrasound may be helpful in defining subtle abnormalities of the bile ducts and locating intraductal stones.

Differential Diagnosis

Other abnormal conditions of the biliary system with similar presentation are summarized in Table 22–10. Liver disease (hepatitis, abscess, or tumor) can cause similar symptoms or signs. Peptic disease, reflux esophagitis, paraesophageal hiatal hernia, cardiac disease, and pneumomediastinum must be considered when the pain is epigastric or substernal in location. Renal or pancreatic disease is a possible explanation if the pain is localized to the right flank or mid back. Subcapsular or suprapapillary lesions of the liver (abscess, tumor, or hematoma) or right lower lobe infiltrate may also be a cause of nontraumatic right shoulder pain.

Complications

Major problems are related to stone impaction in either the cystic or common duct, which may lead to stricture formation or perforation. Acute distention and subsequent perforation of the gallbladder may occur when gallstones cause obstruction of the cystic duct. Stones impacted at the level of the ampulla hepatopancreatica often cause gallstone pancreatitis.

Treatment

Symptomatic cholelithiasis is treated by laparoscopic cholecystectomy or open cholecystectomy in selected cases. Intraoperative cholangiography via the cystic duct is

recommended so that the physician can be certain the biliary system is free of retained stones. Calculi in the extrahepatic bile ducts may be removed at ERCP.

Gallstones developing in premature infants on parenteral nutrition can be followed by ultrasound examination. Most of the infants are asymptomatic, and the stones will resolve in 3–36 months. Gallstone dissolution using cholelitholytics (UDCA) or mechanical means (lithotripsy) has not been approved for children. Asymptomatic gallstones do not usually require treatment, as less than 20% will eventually cause problems.

» Prognosis
The prognosis is excellent in uncomplicated cases that come to standard or laparoscopic cholecystectomy.

2. Primary Sclerosing Cholangitis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

» Pruritus and jaundice.
» Elevated GGT.
» Associated with inflammatory bowel disease.
» Abnormal ERCP or MRCP.

General Considerations
Primary sclerosing cholangitis (PSC) is a progressive liver disease characterized by chronic inflammation and fibrosis of the intrahepatic and/or extrahepatic bile ducts, leading to fibrotic strictures and saccular dilations of all or parts of the biliary tree. The etiology of PSC is likely multifactorial, including genetic predispositions, with alterations in innate and autoimmunity. PSC is more common in males, and has a strong relationship to inflammatory bowel disease, particularly ulcerative colitis. A PSC-like condition can also be seen with histiocytosis X, autoimmune hepatitis, IgG4 autoimmune pancreatitis, sicca syndromes, congenital and acquired immunodeficiency syndromes, and cystic fibrosis. Sclerosing cholangitis due to cryptosporidia may occur in immunodeficiency syndromes.

» Clinical Findings
A. Symptoms and Signs
PSC often has an insidious onset and may be asymptomatic. Clinical symptoms may include abdominal pain, fatigue, pruritus, jaundice, and weight loss. Acholic stools, jaundice steatorrhea hepatomegaly and splenomegaly can occur.

B. Laboratory Findings
The earliest finding may be asymptomatic elevation of the GGT. Subsequent laboratory abnormalities include elevated levels of alkaline phosphatase and bile acids. Later, cholestatic jaundice and elevated AST and ALT may occur. Markers of autoimmune liver disease (ANA and ASMA) are often found, but are not specific for PSC and may actually be due to concurrent overlap with autoimmune hepatitis (overlap syndrome or autoimmune cholangitis).

C. Imaging
Ultrasound is often normal in PSC, but may detect dilated bile ducts related to dominant biliary strictures. MRCP is the diagnostic study of choice, demonstrating irregularities of the biliary tree, including saccular dilation of normal intrahepatic bile ducts with segmental strictures (“beads on a string”), dominant strictures of large ducts or “pruning” of the smaller bile duct branches. ERCP may be more sensitive for the diagnosis of irregularities of the intrahepatic biliary tree and allow for therapeutic interventions.

Differential Diagnosis
The differential diagnosis includes infectious hepatitis, secondary sclerosing cholangitis, AIH, progressive familial intrahepatic cholestasis type 3, cystic fibrosis, choledochal cyst, or other anomalies of the biliary tree, including Caroli disease (see Table 22–10).

Complications
Complications include refractory pruritus, bacterial cholangitis, biliary fibrosis, cirrhosis and complications of portal hypertension. Slow progression to end-stage liver disease is likely, and patients are at increased risk of cholangiocarcinoma.

Treatment
Treatment of PSC focuses on supportive care. UDCA is often used in pediatrics, though high doses may worsen disease in adults. Pruritus may improve with UDCA, rifampin or naltrexone. Oral vancomycin has been reported to be effective in alleviating symptoms and delaying progression,
but multicenter trials are necessary to be conclusive. Patients with autoimmune sclerosing cholangitis or IgG4 cholangitis should benefit from treatment with corticosteroids and azathioprine. Antibiotic treatment of cholangitis and dilation and stenting of dominant bile duct strictures can reduce symptoms. Liver transplantation is effective for patients with end-stage complications, but the disease may recur in up to 20% after transplant.

**Prognosis**

The majority of patients will eventually require liver transplantation in adulthood. PSC is the fifth leading indication for liver transplantation in adults in the United States.

---

**3. Other Biliary Tract Disorders**

For a schematic representation of the various types of choledochal cysts, see Figure 22-1. For summary information on acute hydrops, choledochal cyst, acalculous cholecystitis, Caroli disease, biliary dyskinesia, and congenital hepatic fibrosis, see Table 22-10.

---

**PYOGENIC & AMEBIC LIVER ABSCESS**

#### Essentials of Diagnosis & Typical Features

- Fever and painful enlarged liver.
- Ultrasound of liver demonstrating an abscess.
- Positive serum ameba antibody or positive bacterial culture of abscess fluid.

#### General Considerations

Pyogenic liver abscesses are rare in developed countries, but remain a significant issue in developing countries. The most common cause is *S aureus*, with enteric bacteria less common; fungal abscesses also occur. The resulting lesion tends to be solitary and located in the right hepatic lobe. Unusual causes include omphalitis, subacute infectious endocarditis, pyelonephritis, Crohn disease, and perinephric abscess. In immunocompromised patients, *S aureus*, gram-negative organisms, and fungi may seed the liver from the arterial system. Multiple pyogenic liver abscesses are associated with severe sepsis. Children receiving anti-inflammatory and immunosuppressive agents and children with defects in white blood cell function (chronic granulomatous disease) are prone to pyogenic hepatic abscesses, especially those caused by *S aureus*.

Amebic liver abscess can occur when *Entamoeba histolytica* invasion occurs via the large bowel, although a history of diarrhea (colitis-like picture) is not always obtained.

#### Clinical Findings

**A. History**

With any liver abscess, nonspecific complaints of fever, chills, malaise, and abdominal pain are frequent. Amebic liver abscess is rare in children. An increased risk is associated with travel in areas of endemic infection (Mexico, Southeast Asia) within 5 months of presentation.

**B. Symptoms and Signs**

Weight loss is very common, especially when diagnosis is delayed. A few patients have shaking chills and jaundice. The dominant complaint is a constant dull pain over an enlarged liver that is tender to palpation. An elevated hemidiaphragm with reduced or absent respiratory excursion may be demonstrated on physical examination and confirmed by fluoroscopy.
Fever and abdominal pain are the two most common symptoms of amebic liver abscess. Abdominal tenderness and hepatomegaly are present in over 50%. An occasional prodrome may include cough, dyspnea, and shoulder pain when rupture of the abscess into the right chest occurs.

C. Laboratory Findings

Laboratory studies show leukocytosis and, at times, anemia. LFTs may be normal or reveal mild elevation of transaminases and alkaline phosphatase. Early in the course, LFTs may suggest mild hepatitis. Blood cultures may be positive. The distinction between pyogenic and amebic abscesses in developed countries is best made by indirect hemagglutination test for specific antibody (which is positive in more than 95% of patients with amebic liver disease) and the prompt clinical response of the latter to antiamebic therapy (metronidazole). Examination of material obtained by needle aspiration of the abscess using ultrasound guidance is often diagnostic.

D. Imaging

Ultrasound liver scan is the most useful diagnostic aid in evaluating pyogenic and amebic abscesses, detecting lesions as small as 1–2 cm. MRI, CT, or nuclear scanning with gallium or technetium sulfur colloid may be useful in differentiating tumor or hydatid cyst. Consolidation of the right lower lobe of the lung is common (10%–30% of patients) in amebic abscess.

Differential Diagnosis

Hepatitis, hepatoma, hydatid cyst, gallbladder disease, or biliary tract infections can mimic liver abscess. Subphrenic abscesses, empyema, and pneumonia may give a similar picture. Inflammatory disease of the intestines or of the biliary system may be complicated by liver abscess.

Complications

Spontaneous rupture of the abscess may occur with extension of infection into the subphrenic space, thorax, peritoneal cavity, and, occasionally, the pericardium. Bronchopleural fistula with large sputum production and hemoptysis can develop in severe cases. Simultaneously, the amebic liver abscess may be secondarily infected with bacteria (in 10%–20% of patients). Metastatic hematogenous spread to the lungs and the brain has been reported.

Treatment

Small bacterial liver abscesses (< 5 cm) or those with a solid appearance can be treated medically. Ultrasound- or CT-guided percutaneous needle aspiration for aerobic and anaerobic culture with simultaneous placement of a catheter for drainage, combined with appropriate antibiotic therapy, is the treatment of choice for solitary larger or liquid pyogenic liver abscess. Multiple liver abscesses may also be treated successfully by this method. Surgical intervention may be indicated if rupture occurs outside the capsule of the liver or if enterohemorrhagic fistulae are suspected.

Amebic abscesses in uncomplicated cases should be treated with oral metronidazole, 35–50 mg/kg/day, in three divided doses for 10 days. Intravenous metronidazole can be used for patients unable to take oral medication. Needle aspiration or surgical drainage is indicated for failure of medical management or cysts greater than 10 cm. Once oral feedings can be tolerated, a luminal amebicide such as iodoquinol should be initiated. Resolution of the abscess cavity occurs over 3–6 months.

Prognosis

With drainage and antibiotics, the cure rate is about 90%. Mortality rates have improved, but remain at 4% for pyogenic liver abscess, especially with extrahepatic complications, and less than 1% for amebic abscess.

LIVER TUMORS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Abdominal enlargement and pain, weight loss, anemia.
- Hepatomegaly with or without a definable mass.
- Mass lesion on imaging studies.
- Laparotomy and tissue biopsy.

General Considerations

Primary neoplasms of the liver represent 0.3%–5% of all solid tumors in children. Of these, two-thirds are malignant, with hepatoblastoma being most common (79% of all pediatric liver cancers). Hepatoblastoma typically occurs in children ages 6 months to 3 years, with a male predominance. Most children present with a symptomatic abdominal mass,
though with more advanced disease, weight loss, anorexia, abdominal pain and emesis may occur. Children with Beckwith-Wiedemann syndrome and familial adenomatosis polyposis coli are at increased risk of hepatoblastoma, and should undergo routine screening with α-fetoprotein determinations and abdominal ultrasound until the age of 5 years. In addition, low-birth-weight infants (<1000 g) have a 15 times increased risk of hepatoblastoma, as compared to infants weighing more than 2500 g. Pathologic differentiation from hepatocellular carcinoma, the other major malignant tumor of the liver, may be difficult.

Hepatocellular carcinoma most commonly occurs between the ages of 10 and 12 years and is more common in males. Children are more likely to be symptomatic, with abdominal distension, pain, and advanced disease, including anorexia and weight loss, at presentation. Patients with chronic HBV or HCV infection, cirrhosis, glycogen storage disease type I, tyrosinemia, and α1-antitrypsin deficiency are at increased risk for developing hepatocellular carcinoma. The late development of hepatocellular carcinoma in patients receiving androgens for treatment of Fanconi syndrome and aplastic anemia must also be kept in mind. The use of anabolic steroids by the liver. Leydig cell hyperplasia without the latter a consequence of increased aromatization of circulating androgens poses a risk of hepatic neoplasia. In addition, Wilms tumors, neuroblastoma and lymphoma may all metastasize to the liver.

Clinical Findings

A. History

Noticeable abdominal distension, with or without pain, is the most constant feature. A parent may note a bulge in the upper abdomen or report feeling a hard mass. Constitutional symptoms (eg, anorexia, weight loss, fatigue, fever, and chills) may be present. Jaundice or pruritus may be present if obstruction of the biliary tree occurs. Virilization has been reported as a consequence of gonadotropic activity of tumors. Feminization with bilateral gynecomastia may occur in association with high estradiol levels in the blood, the latter a consequence of increased aromatization of circulating androgens by the liver. Leydig cell hyperplasia without spermatogenesis has also been reported.

B. Symptoms and Signs

Weight loss, pallor, and abdominal pain in association with a large abdomen are common. Physical examination reveals hepatomegaly with or without a definite tumor mass, usually to the right of the midline. In the absence of cirrhosis, signs of chronic liver disease are usually absent.

C. Laboratory Findings

Normal LFTs are the rule. Anemia frequently occurs, especially in cases of hepatoblastoma. α-Fetoprotein levels are typically elevated, especially in hepatoblastoma. Estradiol levels are sometimes elevated. Tissue diagnosis is best obtained at laparotomy, although ultrasound- or CT-guided needle biopsy of the liver mass can be used.

D. Imaging

Ultrasoundography, CT, and MRI are useful for diagnosis, staging, and following tumor response to therapy. A chest CT is generally part of the preoperative workup to evaluate metastatic disease.

Differential Diagnosis

In the absence of a palpable mass, the differential diagnosis is that of hepatomegaly with or without anemia or jaundice. Hematologic and nutritional conditions should be ruled out, as well as HBV and HCV infection, α1-antitrypsin deficiency disease, lipid storage diseases, histiciocytoxis X, glycogen storage disease, tyrosinemia, congenital hepatic fibrosis, cysts, adenoma, focal nodular hyperplasia, and hemangiomas. If fever is present, hepatic abscess (pyogenic or amebic) must be considered. Veno-occlusive disease and hepatic vein thrombosis are rare possibilities. Tumors in the left lobe may be mistaken for pancreatic pseudocysts.

Complications

With progressive enlargement of the tumor, abdominal discomfort, ascites, respiratory difficulty, and widespread metastases (especially to the lungs and the abdominal lymph nodes) are the rule. Rupture of the neoplastic liver and intraperitoneal hemorrhage have been reported.

Treatment

For tumors that are resectable, an aggressive surgical approach with complete resection of the lesion offers the only chance for cure. Individual lung metastases should also be surgically resected. Radiotherapy and chemotherapy have been disappointing in the treatment of hepatocellular carcinoma, although hepatoblastomas are generally more responsive. Chemotherapy may be used for initial cytoreduction of tumors (especially hepatoblastoma) found to be unresectable at the time of primary surgery (see Chapter 31 for additional discussion). Liver transplantation can be an option in hepatoblastoma with unresectable disease limited to the liver, with an 85% 10-year survival. For hepatocellular carcinoma, the survival rate is poor due to the typically advanced stage at diagnosis. The survival rate may be better for those patients in whom the tumor is incidental to another disorder (tyrosinemia, biliary atresia, cirrhosis) or is less than a total of 7 cm diameter without vascular invasion. In HBV-endemic areas, childhood HBV vaccination has reduced the incidence of hepatocellular carcinoma.
CHAPTER 22

Prognosis

If the tumor is completely removed, the survival rate is 90% for hepatoblastoma and 33% for hepatocellular carcinoma. If metastases that cannot be surgically resected are present, survival is reduced to 40% for hepatoblastoma. In well-selected candidates with unresectable hepatoblastoma, survival after liver transplantation approaches 65%.

HCC, hepatocellular carcinoma; PFIC, progressive familial intrahepatic cholestasis.

Orthotopic liver transplantation is indicated in children with end-stage liver disease, acute fulminant hepatic failure, or complications from metabolic liver disorders. Approximately 600 pediatric liver transplants are performed annually, with excellent 1-year (83%–91%) and 5-year (82%–84%) survival rates. The multitude of immunosuppression options, ability to individualize immunosuppression, improved candidate selection, refinements in surgical techniques, anticipatory monitoring for complications (eg, CMV and EBV infections, hypertension, renal dysfunction, and dyslipidemias) and experience in postoperative management have all contributed to improved outcomes over time. The major indications for childhood transplantation are shown in Table 22–11.

Children who are potential candidates for liver transplantation should be referred to a pediatric transplant center early for evaluation. In addition to full-sized cadaveric organs, children may also receive reduced segment or split cadaveric livers and live donor transplants, all of which have expanded the potential donor pool. Lifetime immunosuppression therapy, using combinations of tacrolimus, cyclosporine, prednisone, azathioprine, mycophenolate mofetil, or sirolimus, with its incumbent risks, is generally necessary to prevent rejection. Small studies have examined the potential for complete immunosuppression withdrawal, with a more definitive multicenter study currently underway. Currently, the minimal amount of immunosuppression that will prevent allograft rejection should be chosen. The overall quality of life for children with a transplanted liver appears to be excellent. There is an increased risk (up to 25%) of renal dysfunction and low intelligence scores. The lifelong risk of EBV-induced lymphoproliferative disease, which is approximately 5%, is related to age and EBV exposure status at time of transplantation, and intensity of immunosuppression. Various protocols are being tested for prevention and treatment of lymphoproliferative disease.

PANCREATIC DISORDERS

ACUTE PANCREATITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Epigastric abdominal pain radiating to the back.
- Nausea and vomiting.
- Elevated serum amylase and lipase.
- Evidence of pancreatic inflammation by CT or ultrasound.
General Considerations

The incidence of acute pancreatitis in children is now about 1 per 10,000. Acute pancreatitis is defined as at least two of the following three: abdominal pain consistent with acute pancreatitis; amylase and/or lipase greater than three times the upper limit of normal; and US, CT or MRI imaging consistent with acute pancreatitis. Most cases of acute pancreatitis are the result of drugs, viral infections, systemic diseases, abdominal trauma, or obstruction of pancreatic flow. More than 20% are idiopathic. Causes of pancreatic obstruction include stones, choledochal cyst, tumors of the duodenum, pancreas divisum, and ascariasis. Acute pancreatitis has been seen following treatment with sulfasalazine, thiazides, valproic acid, aza-thioprine, mercaptourine, asparaginase, antiretroviral drugs, high-dose corticosteroids, and other drugs. It may also occur in cystic fibrosis, systemic lupus erythematosus, α1-antitrypsin deficiency, diabetes mellitus, Crohn disease, glycogen storage disease type I, hyperlipidemia types I and V, hyperparathyroidism, Henoch-Schönlein purpura, Reye syndrome, organic acidopathies, Kawasaki disease, or chronic renal failure; during rapid refeeding in cases of malnutrition; following spinal fusion surgery; and familial. Alcohol-induced pancreatitis should be considered in the teenage patient.

Clinical Findings

A. History

An acute onset of persistent (hours to days), moderate to severe upper abdominal and midabdominal pain occasionally referred to the back, frequently associated with vomiting, or nausea is the common presenting picture.

B. Symptoms and Signs

The abdomen is tender, but not rigid, and bowel sounds are diminished, suggesting peritoneal irritation. Abdominal distention is common in infants and younger children and classic symptoms of abdominal pain, tenderness, and nausea are less common in this age group. Jaundice is unusual. Ascites may be noted, and a left-sided pleural effusion is present in some patients. Periumbilical and flank bruising indicate hemorrhagic pancreatitis.

C. Laboratory Findings

An elevated serum amylase or lipase (more than three times normal) is the key laboratory finding. The elevated serum lipase persists longer than serum amylase. Infants younger than 6 months may not have an elevated amylase or lipase. In this setting, an elevated immunoreactive trypsinogen may be more sensitive. Pancreatic lipase can help differentiate nonpancreatic causes (eg, salivary, intestinal, or tuboovarian) of serum amylase elevation. Leukocytosis, hyperglycemia (serum glucose > 300 mg/dL), hypocalcemia, falling hematocrit, rising blood urea nitrogen, hypoxemia, and acidosis may all occur in severe cases and imply a poor prognosis.

D. Imaging

Ultrasoundography is the initial imaging of choice and is primarily used to assess for biliary tract disease leading to pancreatitis, but can show decreased echodensity of the pancreas in comparison with the left lobe of the liver. The pancreas is often difficult to image with ultrasound due to overlying gas. CT scanning images the pancreas more consistently and is better for detecting pancreatic phlegmon, pseudocyst, necrosis, or abscess formation. The computed tomography severity index (CTSI) is useful in identifying patients at increased risk for serious complications. ERCP or MRCP may be useful in confirming patency of the main pancreatic duct in cases of abdominal trauma; in recurrent acute pancreatitis; or in revealing stones, ductal strictures, and pancreas divisum.

Differential Diagnosis

Other causes of acute upper abdominal pain include gastroenteritis; peptic ulcer disease; duodenal ulcer; hepatitis; liver abscess; cholelithiasis; cholecystitis; choledocholithiasis; acute gastroenteritis or atypical appendicitis; pneumonia; volvulus; intussusception; and nonaccidental trauma.

Complications

Early complications include shock, fluid and electrolyte disturbances, ileus, acute respiratory distress syndrome, and hypocalcemia. Hypervolemia due to renal insufficiency related to renal tubular necrosis may occur. The gastrointestinal, neurologic, musculoskeletal, hepatobiliary, dermatologic, and hematologic systems may also be involved. Early predictors of a more aggressive course include renal dysfunction, significant fluid requirements, and multisystem organ dysfunction. Around 5%–20% of patients can develop a pseudocyst 1–4 weeks later that may be asymptomatic or present with recurrence of abdominal pain and rise in the serum amylase. Up to 60%–70% of pseudocysts resolve spontaneously. Infection, hemorrhage, rupture, or fistulization may occur. Phlegmon formation is rare in children, but when present may extend from the gland into the retroperitoneum or into the lesser sac. Most regress, but some require drainage. Infection may occur in this inflammatory mass. Pancreatic abscess formation, which is rare (3%–5%), develops 2–3 weeks after the initial insult. Fever, leukocytosis, and pain suggest this complication; diagnosis is made by ultrasound or CT scanning. Approximately 30% will develop recurrent acute pancreatitis. Chronic pancreatitis, exocrine or endocrine pancreatic insufficiency, and pancreatic lithiasis are rare sequelae of acute pancreatitis.
CHAPTER 22

Treatment

Medical management includes careful attention to fluid, electrolytes, and respiratory status. Data in adults suggest lactated ringers is preferred for volume expansion in acute pancreatitis. Gastric decompression may be helpful if there is significant vomiting. Pain should be controlled with opioids. Nutrition is preferentially provided by the enteral (jejunal or gastric) route. Broad-spectrum antibiotic coverage is useful only in necrotizing pancreatitis. Drugs known to produce acute pancreatitis should be discontinued. Surgical treatment is reserved for traumatic disruption of the gland, intraductal stone, other anatomic obstructive lesions, and unresolved or infected pseudocysts or abscesses. Early endoscopic decompression of the biliary system reduces the morbidity associated with pancreatitis caused by obstruction of the common bile duct.

Prognosis

In the pediatric age group, the prognosis is surprisingly good with conservative management with mortality less than 0.4%.

CHRONIC PANCREATITIS

Chronic pancreatitis is differentiated from acute pancreatitis in that the pancreas remains structurally or functionally abnormal after an attack.

The causes are multiple and can be divided into toxic-metabolic (eg, alcohol, chronic renal failure, hypercalcemia), idiopathic, genetic (increasingly recognized in children and adolescents), autoimmune, recurrent and severe acute pancreatitis, and obstructive pancreatitis (eg, pancreas divisum, choledochal cyst).

Clinical Findings

A. History

The diagnosis often is delayed by the nonspecificity of symptoms and the lack of persistent laboratory abnormalities. There is usually a prolonged history of recurrent upper abdominal pain of variable severity. Radiation of the pain into the back is a frequent complaint.

B. Symptoms and Signs

Fever and vomiting are rare. Diarrhea, due to steatorrhea, and symptoms of diabetes may develop later in the course. Malnutrition due to acquired exocrine pancreatic insufficiency may also occur.

C. Laboratory Findings

Serum amylase and lipase levels are usually elevated during early acute attacks, but are often normal in the chronic phase. Pancreatic insufficiency may be diagnosed by demonstration of a low fecal pancreatic elastase 1. Mutations of the cationic trypsinogen gene, the pancreatic secretory trypsin inhibitor, the cystic fibrosis transmembrane conductance regulator (CFTR), carboxypeptidase A1 and chymotrypsin C are associated with recurrent acute and chronic pancreatitis. Elevated blood glucose and glycohemoglobin levels and glycosuria frequently occur in protracted disease. Sweat chloride should be checked for cystic fibrosis, α1-antitrypsin level or phenotype, and serum calcium for hyperparathyroidism.

D. Imaging

Radiographs of the abdomen may show pancreatic calcifications in up to 30% of patients. Ultrasound or CT examination demonstrates an abnormal gland (enlargement or atrophy), ductal dilation, and calculi in up to 80%. CT is the initial imaging procedure of choice. MRCP or ERCP can show ductal dilation, stones, strictures, or stenotic segments. Endoscopic ultrasound in the diagnosis and staging of chronic pancreatitis is being evaluated.

Differential Diagnosis

Other causes of recurrent abdominal pain must be considered. Specific causes of pancreatitis such as autoimmune pancreatitis, hyperparathyroidism; systemic lupus erythematosus; infectious disease; α1-antitrypsin deficiency; and ductal obstruction by tumors, stones, or helminths must be excluded by appropriate tests.

Complications

Disabling abdominal pain, steatorrhea, malnutrition, pancreatic pseudocysts, and diabetes are the most frequent long-term complications. Pancreatic carcinoma occurs more frequently in patients with chronic pancreatitis, and in up to 40% of patients with hereditary pancreatitis by age 70.

Treatment

Medical management of acute attacks is indicated (see section on Acute Pancreatitis, earlier). If ductal obstruction is strongly suspected, endoscopic therapy (balloon dilation, stenting, stone removal, or sphincterotomy) should be pursued.
Relapses occur in most patients. Pancreatic enzyme therapy should be used in patients with pancreatic insufficiency. Antioxidant therapy is being investigated. Pseudocysts may be marsupialized to the surface or drained into the stomach or into a loop of jejunum if they fail to regress spontaneously. Lateral pancreaticojejunostomy or the Frey procedure can reduce pain in pediatric patients with a dilated pancreatic duct and may prevent or delay progression of functional pancreatic impairment. Pancreatectomy and islet cell autotransplantation has been used in selected cases of chronic pancreatitis.

Prognosis

In the absence of a correctable lesion, the prognosis is not good. Disabling episodes of pain, pancreatic insufficiency, diabetes, and pancreatic cancer may ensue. Narcotic addiction and suicide are risks in teenagers with disabling disease.

Laboratory findings include a normal sweat chloride; low fecal pancreatic elastase 1; and low to absent pancreatic lipase, amylase, and trypsin levels on duodenal intubation. Each disorder has several associated clinical features that aid in the differential diagnosis. In Shwachman-Diamond syndrome, pancreatic exocrine hypoplasia with widespread fatty replacement of the glandular acinar tissue is associated with neutropenia because of maturational arrest of the granulocyte series. Bone marrow failure is seen in one-third. Metaphyseal dysostosis and an elevated fetal hemoglobin level are common; immunoglobulin deficiency and hepatic dysfunction are also reported. CT examination of the pancreas demonstrates the widespread fatty replacement. Genotyping of the SBDS gene is available. Serum immunoreactive trypsinogen levels are extremely low.

Other associations of exocrine pancreatic insufficiency include (1) aplastic anemia, aplasia cutis, deafness (Johanson-Blizzard syndrome); (2) sideroblastic anemia, developmental delay, seizures, and liver dysfunction (Pearson bone marrow pancreas syndrome); (3) duodenal atresia or stenosis; (4) malnutrition; and (5) pancreatic hypoplasia or agenesis.

The complications and sequelae of exocrine pancreatic insufficiency are malnutrition, diarrhea, and growth failure. The degree of steatorrhea may lessen with age. Intragastric lipolysis by lingual lipase may compensate in patients with low or absent pancreatic function. In Shwachman-Diamond syndrome, short stature and bony dysplasias are problematic. Increased numbers of infections may result from chronic neutropenia and the reduced neutrophil mobility that is present in many patients. An increased incidence of leukemia has been noted in these patients; thus patients with myelodysplasia syndrome should be considered for hematopoietic stem cell transplantation.

Pancreatic enzyme and fat-soluble vitamin replacement are required therapy in most patients. The prognosis appears to be good for those able to survive the increased number of bacterial infections early in life and lack severe associated defects.

ISOLATED EXOCRINE PANCREATIC ENZYME DEFECT

Premature infants and most newborns produce little, if any, pancreatic amylase following meals or exogenous hormonal stimulation. This temporary physiologic insufficiency may persist for the first 3–6 months of life and be responsible for diarrhea when complex carbohydrates (cereals) are introduced early in the diet.

Congenital pancreatic lipase deficiency and congenital colipase deficiency are extremely rare disorders, causing diarrhea and variable malnutrition with malabsorption of dietary fat and fat-soluble vitamins. In these cases, the sweat chloride level is normal and neutropenia is absent. Treatment is oral replacement of pancreatic enzymes and a low-fat diet or formula containing medium-chain triglycerides.

Exocrine pancreatic insufficiency of proteolytic enzymes (eg, trypsinogen, trypsin, chymotrypsin) is caused by entero-kinase deficiency, a duodenal mucosal enzyme required for activation of the pancreatic proenzymes. These patients present with malnutrition associated with hypoproteinemia and edema. Similar to lipase and colipase deficiencies, the sweat test and neutrophil counts are normal. Patients with entero-kinase deficiency respond to pancreatic enzyme replacement therapy and feeding formulas that contain a casein hydrolysate (eg, Nutramigen, Pregestimil).

PANCREATIC TUMORS

Pancreatic tumors, whether benign or malignant, are rare. The majority of patients with malignant tumors present with abdominal pain. Pancreatic tumors most often arise from ductal or acinar epithelium (malignant adenocarcinoma) or from islet (endocrine) components within the gland, such as the benign insulinoma (adenoma) derived from β cells. Other pancreatic tumors originate from these pluripotential endocrine cells (eg, gastrinoma, VIPoma, glucagonoma), and produce diverse symptoms, because they release biologically active polypeptides from this ectopic location. The clinical features of these tumors are summarized in Table 22–13. The differential diagnosis of pancreatic tumors includes Wilms tumor, neuroblastoma, and malignant lymphoma. In older children, endoscopic ultrasonography can aid in localizing these tumors.

| Table 22–13. Pancreatic tumors. |
|-------------------------------|-------------------------------|-------------------------------|-------------------------------|-------------------------------|
| **Age** | **Major Findings** | **Diagnosis** | **Treatment** | **Associated Conditions** |
| Insulinoma | Any age | Hypoglycemia, seizures; high serum insulin; weight gain; abdominal pain and mass infrequent | CT scan, MRI, PET, EUS, SRS | Surgery, diazoxide, SSTA | MEN1 |
| Adenocarcinoma | Any age | Epigastric pain, mass, weight loss, anemia, biliary obstruction | Ultrasound, CT scan, MRI, EUS | Surgery | Chronic pancreatitis |
| Gastrinoma | > 5–8 y | Male sex, gastric hypersecretion, peptic symptoms, multiple ulcers, gastrointestinal bleeding, anemia, diarrhea | Elevated fasting gastrin and postsecretin suppression test (> 300 pg/mL), CT scan, MRI, EUS, SRS, laparotomy | PPI, surgical resection, total gastrectomy, SSTA | Zollinger-Ellison syndrome, MEN1, neurofibromatosis |
| VIPoma | Any age (more common 2–4 y old) | Secretory diarrhea, hypokalemia, hypochlorhydria, weight loss, flushing | Elevated VIP levels (> 75 pg/mL); sometimes, elevated serum gastrin and pancreatic polypeptide; CT, EUS, SRS | Surgery, SSTA, IV fluids |
| Glucagonoma | Older patients | Diabetes, necrolytic migratory erythema, diarrhea, anemia, thrombotic events, depression | Elevated glucagon, hyperglycemia, gastrin, VIP, CT, MRI, EUS, SRS | Surgery, SSTA |

CT, computed tomography; EUS, endoscopic ultrasound; IV, intravenous; MEN1, multiple endocrine neoplasia syndrome type 1; MRI, magnetic resonance imaging; PET, Positron emission tomography; PPI, proton pump inhibitor; SRS, somatostatin-receptor scintigraphy; SSTA, somatostatin analogue; VIP, vasoactive intestinal polypeptide.

REGULATION OF BODY FLUIDS, ELECTROLYTES, & TONICITY

Total body water (TBW) constitutes 50%–75% of the total body mass, depending on age, sex, and fat content. After an initial brisk postnatal diuresis, the TBW slowly decreases to the adult range near puberty. TBW is divided into the intracellular and extracellular spaces. Intracellular fluid (ICF) accounts for two-thirds of the TBW and extracellular fluid (ECF) for one-third. The ECF is further compartmentalized into plasma (intravascular) volume and interstitial fluid (ISF).

The principal constituents of plasma are sodium, chloride, bicarbonate, and protein (primarily albumin). The ISF is similar to plasma but lacks significant amounts of protein. Conversely, the ICF is rich in potassium, magnesium, phosphates, sulfates, and protein.

An understanding of osmotic shifts between the ECF and ICF is fundamental to understanding disorders of fluid balance. Iso-osmolality is generally maintained between fluid compartments. Because the cell membrane is water-permeable, abnormal fluid shifts occur if the concentration of solutes that cannot permeate the cell membrane in the ECF does not equal the concentration of such solutes in the ICF. Thus, NaCl, mannitol, and glucose (in the setting of hyperglycemia) remain restricted to the ECF space and contribute effective osmoles by obligating water to remain in or be drawn into the ECF compartment. In contrast, a freely permeable solute such as urea does not contribute effective osmoles because it is not restricted to the ECF and readily crosses cell membranes. Tonicity, or effective osmolality, differs from measured osmolality in that it accounts only for osmotically active impermeable solutes rather than all osmotically active solutes, including those that are permeable to cell membranes. Osmolality may be estimated by the following formula:

\[ \text{mOsm/kg} = 2[\text{Na}^+ (\text{mEq/L})] + \frac{\text{Glucose (mg/dL)}}{18} + \frac{\text{BUN (mg/dL)}}{2.8} \]

Although osmolality and osmolarity differ, the former being an expression of osmotic activity per weight (kg) and the latter per volume (L) of solution, for clinical purposes they are similar and occasionally used interchangeably. Oncotic pressure, or colloid osmotic pressure, represents the osmotic activity of macromolecular constituents such as albumin in the plasma and body fluids. The importance of albumin in maintaining intravascular volume status is reflected in the setting of the nephrotic syndrome, protein losing enteropathy, and other low serum albumin states wherein fluids accumulate in the interstitial compartment leading to edema.

The principal mechanisms that regulate ECF volume and tonicity are thirst, vasopressin or antidiuretic hormone (ADH), aldosterone, and atrial natriuretic peptide (ANP), the latter three exerting their influence by their effects on renal water and sodium handling.

Thirst

Water intake is commonly determined by cultural and behavioral factors. Thirst is not physiologically stimulated until plasma osmolality reaches 290 mOsm/kg, a level at which ADH release induces maximal antidiuresis. Thirst provides control over a wide range of fluid states and allows maintenance of appropriate intravascular volume, even in polyuric states (such as central or nephrogenic DI, or obstructive uropathy). An adequate thirst mechanism is central to maintaining adequate fluid balance.
Antidiuretic Hormone

In the kidney, ADH increases water reabsorption in the cortical and medullary collecting ducts, leading to formation of concentrated urine. In the absence of ADH, dilute urine is produced. Typically, ADH secretion is regulated by the tonicity of body fluids rather than intravascular fluid volume; it becomes detectable at a plasma osmolality of 280 mOsm/kg or greater. Tonicity may, however, be sacrificed to preserve ECF volume (i.e. with hyponatremic dehydration), wherein ADH secretion and renal water retention are maximal, despite comparatively lower plasma osmolality.

Aldosterone

Aldosterone is released from the adrenal cortex in response to (a) decreased effective circulating volume and resultant stimulation of the renin-angiotensin-aldosterone axis or (b) in response to increasing plasma K⁺. Aldosterone enhances renal tubular reabsorption of Na⁺ in exchange for K⁺, and to a lesser degree H⁺. At a constant osmolality, retention of Na⁺ leads to expansion of ECF volume and suppression of aldosterone release.

Atrial Natriuretic Peptide

ANP, a polypeptide hormone secreted principally by the cardiac atria in response to atrial dilation, contributes to regulation of blood volume and blood pressure. ANP inhibits renin secretion and aldosterone synthesis and causes an increase in glomerular filtration rate and renal sodium excretion. ANP also guards against excessive plasma volume expansion in the face of increased ECF volume by shifting fluid from the vascular to the interstitial compartment. ANP inhibits angiotensin II and norepinephrine-induced vasoconstriction and acts in the brain to decrease the desire for salt and suppression of aldosterone release.

ACID-BASE BALANCE

The pH of arterial blood is maintained between 7.38 and 7.42 to ensure that pH-sensitive enzyme systems function normally. Acid-base balance is maintained by interaction of the lungs, kidneys, and systemic buffering systems. Over 50% of the blood’s buffering capacity is provided by the carbonic acid–bicarbonate system, roughly 30% by hemoglobin, and the remainder by phosphates and ammonium. The carbonic acid–bicarbonate system, depicted chemically as

\[ \text{CO}_2 + \text{H}_2\text{O} \leftrightarrow \text{H}_2\text{CO}_3 \leftrightarrow \text{H}^+ + \text{HCO}_3^- \]

interacts via the lungs and kidneys, and in conjunction with the nonbicarbonate systems, to stabilize systemic pH. The concentration of dissolved CO₂ in blood is established by the respiratory system and that of HCO₃⁻ by the kidneys. Disturbances in acid-base balance are initially stabilized by chemical buffering, compensated for by pulmonary or renal regulation of CO₂ or, respectively, and ultimately corrected when the primary cause of the acid-base disturbance is eliminated.

Renal regulation of acid-base balance is accomplished by the reabsorption of filtered HCO₃⁻, primarily in the proximal tubule, and the excretion of H⁺ or HCO₃⁻ in the distal nephron to match the net input of acid or base. When urine is alkalinated, HCO₃⁻ enters the kidney and is ultimately lost in the urine. However, urinary alkalinization will not occur if there is a deficiency of urine Na⁺ or K⁺, as electroneutrality must be maintained. In contrast, the urine may be acidified if an absolute or relative decrease occurs in systemic HCO₃⁻. In this setting, proximal tubular HCO₃⁻ reabsorption and distal tubular H⁺ excretion are maximal. A “paradoxical aciduria” with low urinary pH may be seen in the setting of hypokalemic metabolic alkalosis and systemic K⁺ depletion wherein H⁺ is exchanged and excreted in preference to K⁺ in response to mineralocorticoid. Some of the processes involved in acid-base regulation are shown in Figure 23–1.

FLUID & ELECTROLYTE MANAGEMENT

Therapy of fluid and electrolyte disorders should be phased to (1) expand the ECF volume and restore tissue perfusion, (2) replenish fluid and electrolyte deficits while correcting attendant acid-base abnormalities, (3) meet the patient’s nutritional needs, and (4) replace ongoing losses.

The cornerstone of therapy involves a detailed understanding of “maintenance” fluid and electrolyte requirements. “Maintenance” requirements call for provision of enough water, glucose, and electrolytes to prevent deterioration of body stores for a euvolemic patient under normal conditions. During short-term parenteral therapy, sufficient glucose is provided to prevent ketosis and limit protein
catabolism, although this usually provides little more than 20% of the patient’s true caloric needs. Prior to the administration of “maintenance” fluids, it is important to consider the patient’s volume status and to determine whether intravenous fluids are truly needed.

Various models have been devised to facilitate calculation of “maintenance” requirements based on body surface area, weight, and caloric expenditure. A system based on caloric expenditure is most helpful, because 1 mL of water is needed for each kilocalorie expended. The system presented in Table 23–1 is based on caloric needs and is applicable to children weighing more than 3 kg.

As depicted in Table 23–1, a child weighing 30 kg would need 1700 kcal or 1700 mL of water daily. If the child received parenteral fluids for 2 days, the fluid would usually contain 5% glucose, which would provide 340 kcal/day, or 20% of the maintenance caloric needs. Maintenance fluid requirements take into account normal insensible water losses (Table 23–2) and water lost in sweat, urine, and stool, and assume the patient to be afebrile, at their true dry weight, and relatively inactive. Thus, if excessive losses occur, standard “maintenance fluids” will be inadequate. In contrast, if losses are reduced for any reason, standard “maintenance fluid” administration would be excessive. Maintenance requirements are greater for low-birth-weight and preterm infants. Table 23–3 lists other factors that commonly alter fluid and caloric needs.

Electrolyte losses occur primarily through the urinary tract and to a lesser degree via the skin and stool. Although maintenance sodium and potassium electrolyte needs have historically been approximated to be in the 3 mEq

Dehydration

Depletion of body fluids is one of the most commonly encountered problems in clinical pediatrics. The clinical evaluation of a child with dehydration, or volume contraction, should focus on the composition and volume of fluid intake and losses (vomiting, diarrhea, urine, “insensible losses”). An updated weight is central to calculating the magnitude of volume depletion. Important clinical features in estimating the degree of dehydration include the capillary refill time, postural blood pressure, and heart rate changes; dryness of the lips and mucous membranes; lack of tears; lack of external jugular venous filling when supine; a sunken fontanelle in an infant; oliguria; and altered mental status (Table 23–5). Children generally respond to a decrease in circulating volume with a compensatory increase in pulse rate and may maintain their blood pressure in the face of severe dehydration. A low or falling blood pressure is, therefore, a late sign of shock in children, and when present should prompt emergent treatment. Salient laboratory parameters include a high urine-specific gravity (in the absence of an underlying renal concentrating defect as seen in diabetes insipidus or chronic obstructive or reflux nephropathy), a relatively greater elevation in blood urea nitrogen than in serum creatinine, a low urinary [Na⁺] excretion (< 20 mEq/L) or fractional excretion of sodium less than 0.1%, and an elevated hematocrit or serum albumin level secondary to hemoconcentration.

Emergent intravenous therapy is indicated when there is evidence of compromised perfusion (inadequate capillary refill, tachycardia, poor color, oliguria, or hypotension). The initial goal is to rapidly expand the plasma volume and to prevent circulatory collapse. A 20-mL/kg bolus of isotonic fluid should be given intravenously as rapidly as possible. Either colloid (5% albumin) or crystalloid (normal saline or Ringer lactate) may be used. Colloid is particularly useful in hypernatremic patients in shock, in malnourished infants, and in neonates. If no intravenous site is available, fluid may be administered intra-osseously through the marrow space of the tibia. If there is no response to the first fluid bolus, a second bolus may be given. When adequate tissue perfusion is demonstrated by improved capillary refill, decreased pulse rate and improved and mental status, deficit replacement may be instituted. If adequate perfusion is not restored after 40 mL/kg of isotonic fluids, other pathologic processes must be considered such as sepsis, occult hemorrhage, or

Na/100 kcal and 2 mEq K/100 kcal range, leading to the common use of hypotonic intravenous fluids with 38 or 77 mEq/L of sodium (¼ and ½ normal saline) and 20 mEq/L of potassium. Over the past 10 years many authors have drawn attention to the serious problem of hospital-acquired hyponatremia in children with the use of hypotonic IV solutions; notably, hyponatremia is the most common electrolyte abnormality in children and affects approximately 25% of hospitalized pediatric patients. Furthermore, the astute clinician will bear in mind the dynamic nature of clinical context in treating patients and that the choice of IV solution (Table 23–4) and rate of infusion must be made on an individual basis and must be reassessed often. A child with profound water loss stools and hypernatremia who is placed on hypotonic IV fluids and whose diarrhea ceases, but is profound water loss stools and hypernatremia who is placed
cardiogenic shock. Isotonic dehydration may be treated by providing half of the remaining fluid deficit over 8 hours and the second half over the ensuing 16 hours in the form of 5% dextrose with 0.45% saline containing 20 mEq/L of KCl. In the presence of metabolic acidosis, potassium acetate may be considered. Maintenance fluids and replacement of ongoing losses should also be provided. Typical electrolyte compositions of various body fluids are depicted in Table 23–6, although it may be necessary to measure the specific constituents of a patient’s fluid losses to guide therapy. If the patient is unable to eat for a prolonged period, nutritional needs must be met through hyperalimentation or enteral tube feedings.

Oral rehydration may be provided to children with mild to moderate dehydration and commercially available solutions provide 45–75 mEq/L of Na⁺, 20–25 mEq/L of K⁺, 30–34 mEq/L of citrate or bicarbonate, and 2%–2.5% of glucose (Table 23–7). Clear liquid beverages found in the home, such as broth, soda, juice, and tea are inappropriate for the treatment of dehydration. Frequent small aliquots (5–15 mL) should be given to provide approximately 50 mL/kg over 4 hours for mild dehydration and up to 100 mL/kg over 6 hours for moderate dehydration. Oral rehydration is contraindicated in children with altered levels of consciousness or respiratory distress who cannot drink freely; in children suspected of having an acute surgical abdomen; in infants with greater than 10% volume depletion; in children with hemodynamic instability; and in the setting of severe hyponatremia ([Na⁺] < 120 mEq/L) or severe respiratory alkalosis.

hypernatremia ([Na⁺] > 160 mEq/L). Failure of oral rehydration due to persistent vomiting or inability to keep up with losses mandates intravenous therapy. Successful oral rehydration requires explicit instructions to caregivers and close clinical follow-up of the child.

The type of dehydration is often characterized by the serum [Na⁺]. If relatively more solute is lost than water, the [Na⁺] falls, and hyponatremic dehydration ([Na⁺] < 130 mEq/L) ensues. This is important clinically because hypotonicity of the plasma contributes to further volume loss from the ECF into the intracellular space. Thus, tissue perfusion is more significantly impaired for a given degree of hyponatremic dehydration than for a comparable degree of isotonic or hypertonic dehydration. It is important to note, however, that significant solute losses also occur in hypernatremic dehydration. Furthermore, because plasma volume is somewhat protected in hypernatremic dehydration, it poses the risk of the clinician underestimating the severity of dehydration. Typical fluid and electrolyte losses associated with each form of dehydration are shown in Table 23–8.

### HYPERSONATREMIA

Hyponatremia may be factitious in the presence of high plasma lipids or proteins, which decrease the percentage of plasma volume that is water. Hyponatremia in the absence of hypotonicity also occurs when an osmotically active solute, such as glucose or mannitol, is added to the ECF. Water drawn from the ICF dilutes the serum [Na⁺] despite isotonicity or hypertonicity.

Patients with hyponatremic dehydration generally demonstrate typical signs and symptoms of dehydration (see Table 23–5), as the vascular space is compromised as water leaves the ECF to maintain osmotic neutrality. The treatment of hyponatremic dehydration is fairly straightforward. The magnitude of the sodium deficit may be calculated by the following formula:

\[
\text{Na⁺ deficit} = (\text{Na⁺ desired} - \text{Na⁺ observed}) \times \text{Bodyweight (kg)} \times 0.6
\]

Half of the deficit is replenished in the first 8 hours of therapy, and the remainder is given over the following 16 hours. Maintenance and replacement fluids should also be provided. The deficit plus maintenance calculations often approximate 5% dextrose with 0.45% or higher saline. The rise in serum [Na⁺] should not exceed 0.5 mEq/L/h or 6–8 mEq/L/24 h unless the patient demonstrates central nervous system (CNS) symptoms that warrant more rapid initial correction. The dangers of too rapid correction of hyponatremia include cerebral dehydration and injury due to fluid shifts from the ICF compartment, a condition known as osmotic demyelination syndrome.

Hypovolemic hyponatremia also occurs in cerebral salt-wasting (CSW) associated with CNS insults, a condition characterized by high urine output and elevated urinary [Na⁺] (> 40 mEq/L) due to an increase in ANP. CSW is a diagnosis of exclusion represented by an inappropriate natriuresis in a patient with a contracted effective circulatory blood volume in the absence of other causes for Na⁺ excretion. This must be distinguished from the syndrome of inappropriate secretion of ADH (SIADH), which may also manifest in CNS conditions and pulmonary disorders (Table 23–9). In contrast to CSW, SIADH is characterized by euvolemic or mild volume expansion and relatively low urine output due to ADH-induced water retention.

ᵃUrine is inappropriately concentrated when it should be maximally dilute with a urine osmolality of <100 mOsm/kg.

ᵇMay be normal or maximally dilute with a urine osmolality of <100 mOsm/kg.
Urinary [Na⁺] is high in both conditions, though generally not as high as in SIADH. It is important to distinguish between these two conditions, because the treatment of cerebral salt wasting involves replacement of urinary salt and water losses, whereas the treatment of SIADH involves water restriction. It is also important to remember that in SIADH patients are not necessarily oliguric, and that their urine does not need to be maximally concentrated but merely inappropriately concentrated for their degree of serum tonicity.

In cases of severe hyponatremia (serum [Na⁺] < 120 mEq/L) with CNS symptoms, intravenous 3% NaCl may be given over 1 hour to raise the [Na⁺] to 120 mEq/L to alleviate CNS manifestations and sequelae. In general, 1 mL/kg of 3% NaCl will raise the serum [Na⁺] by about 1 mEq/L. If 3% NaCl is administered, estimated Na⁺ and fluid deficits should be adjusted accordingly. Further correction should proceed slowly, as outlined earlier.

Hyponatremia is commonly achieved using 5% dextrose with 0.2% saline. If the serum [Na⁺] is not correcting appropriately, the free decrease in serum [Na⁺] is desired (6–8 mEq/L/day). This adequate tissue perfusion using isotonic fluids, a gradual injury may occur. Thus, following the initial restoration of Na⁺ and water and correction of the underlying disorder. Hyponatremia is due to water intoxication is characterized by a maximally dilute urine (specific gravity < 1.003) and is also treated with water restriction.

**HYPERNATREMIA**

Although diarrhea is commonly associated with hypotonic or isonatremic dehydration, hypernatremia may develop in the presence of persistent fever or decreased fluid intake or in response to improperly mixed rehydration solutions. Extreme care is required to treat hypernatremic dehydration appropriately. If the serum [Na⁺] falls precipitously, the osmolality of the ECF drops more rapidly than that of the CNS. Water shifts from the ECF compartment into the CNS to maintain osmotic neutrality. If hypertonicity is corrected too rapidly (a drop in [Na⁺] of > 0.5 mEq/L/h), cerebral edema, seizures, and CNS injury may occur. Thus, following the initial restoration of adequate tissue perfusion using isotonic fluids, a gradual decrease in serum [Na⁺] is desired (6–8 mEq/L/day). This is commonly achieved using 5% dextrose with 0.2% saline to replace the calculated fluid deficit over 48 hours. Maintenance and replacement fluids should also be provided. If the serum [Na⁺] is not correcting appropriately, the free water deficit may be estimated as 4 mL/kg of free water for each milliequivalent of serum [Na⁺] above 145 mEq/L and provided as 5% dextrose over 48 hours. If metabolic acidosis is also present, it must be corrected slowly to avoid CNS irritability. Potassium is provided as indicated—as the acetate salt if necessary. Electrolyte concentrations should be assessed every 2 hours in order to control the decline in serum [Na⁺]. Elevations of blood glucose and blood urea nitrogen may worsen the hyperosmolar state in hypernatremic dehydration and should also be monitored closely. Hyperglycemia is often associated with hypernatremic dehydration and may necessitate lower intravenous glucose concentrations (eg, 2.5%).

Patients with diabetes insipidus, whether nephrogenic or central in origin, are prone to develop profound hypernatremic dehydration as a result of unremitting urinary-free water losses (urine-specific gravity < 1.010), particularly during superimposed gastrointestinal illnesses associated with vomiting or diarrhea. Treatment involves restoration of fluid and electrolyte deficits as described earlier as well as replacement of excessive water losses. Formal water deprivation testing to distinguish responsiveness to ADH should only be done during daylight hours after restoration of normal fluid volume status.

However, if a child presents with marked dehydration and a serum Na⁺ greater than 150 mEq/L, it may prove helpful and timely to obtain a plasma vasopressin level at the time of their initial presentation. The evaluation and treatment of nephrogenic and central diabetes insipidus are discussed in detail in Chapters 24 and 34, respectively.

Hypervolemic hypernatremia (salt poisoning), associated with excess total body salt and water, may occur as a consequence of providing improperly mixed formula, excessive NaCl or NaHCO₃ administration, or as a feature of primary hyperaldosteronism. Treatment includes the use of diuretics, and potentially, concomitant water replacement or even dialysis.

**POTASSIUM DISORDERS**

The predominantly intracellular distribution of potassium is maintained by the actions of Na⁺-K⁺-ATPase in the cell membranes. Potassium is shifted into the ECF and plasma by acidemia and into the ICF in the setting of alkalosis, hypochloremia, or in conjunction with insulin-induced cellular glucose uptake. The ratio of intracellular to extracellular K⁺ is the major determinant of the cellular resting membrane potential and contributes to the action potential in neural and muscular tissue. Abnormalities of K⁺ balance are potentially life threatening. In the kidney, K⁺ is filtered at the glomerulus, reabsorbed in the proximal tubule, and excreted in the distal tubule. Distal tubular K⁺ excretion is regulated primarily by the mineralocorticoid aldosterone. Renal K⁺ excretion is primarily dependent on the urinary flow rate, and continues for significant periods even after the intake of K⁺ is decreased. Thus, by the time urinary [K⁺] decreases, the systemic K⁺ pool has been depleted significantly. In general, the greater the urine flow the greater the urinary K⁺ excretion.

The causes of net K⁺ loss are primarily renal in origin. Gastrointestinal losses through nasogastric suction or vomiting reduce total body K⁺ to some degree. However, the resultant
volume depletion results in an increase in plasma aldosterone, promoting renal excretion of K⁺ in exchange for Na⁺ reclamation to preserve circulatory volume. Diuretics (especially thiazides and loop diuretics), mineralocorticoids, and intrinsic renal tubular diseases (eg, Bartter syndrome) enhance the renal excretion of K⁺. Systemic K⁺ depletion in hypokalemic metabolic acidosis may lead to “paradoxic aciduria” and low urine pH wherein H⁺ is preferentially exchanged for Na⁺ in response to aldosterone. Clinically, hypokalemia is associated with neuromuscular excitability, decreased peristalsis or ileus, hyporeflexia, paralysis, rhabdomyolysis, and arrhythmias. Electrocardiographic changes include flattened T waves, a shortened PR interval, and the appearance of U waves. Arrhythmias associated with hypokalemia include premature ventricular contractions; atrial, nodal, or ventricular tachycardia; and ventricular fibrillation. Hypokalemia increases responsiveness to digitalis and may precipitate overt digitalis toxicity. In the presence of arrhythmias, extreme muscle weakness, or respiratory compromise, intravenous K⁺ should be given. If the patient is hypophosphatemic ([PO₄³⁻] < 2 mg/dL), a phosphate salt may be used. The first priority in the treatment of hypokalemia is the restoration of an adequate serum [K⁺]. Providing maintenance amounts of K⁺ is usually sufficient; however, when the serum [K⁺] is dangerously low and K⁺ must be administered intravenously, it is imperative that the patient have a cardiac monitor. Intravenous K⁺ should generally not be given faster than at a rate of 0.3 mEq/kg/h. Oral K⁺ supplements may be needed for weeks to replenish depleted body stores.

Hyperkalemia—due to decreased renal K⁺ excretion, mineralocorticoid deficiency or unresponsiveness, or K⁺ release from the ICF compartment—is characterized by muscle weakness, paresthesias, and tetany; ascending paralysis; and arrhythmias. Electrocardiographic changes associated with hyperkalemia include peaked T waves, widening of the QRS complex, and arrhythmias such as sinus bradycardia or sinus arrest, atrioventricular block, nodal or idioventricular rhythms, and ventricular tachycardia or fibrillation. The severity of hyperkalemia depends on the electrocardiographic changes, the status of the other electrolytes, and the stability of the underlying disorder. A rhythm strip should be obtained when significant hyperkalemia is suspected. If the serum [K⁺] is less than 6.5 mEq/L, discontinuing K⁺ supplementation may be sufficient if there is no ongoing K⁺ source, such as cell lysis, and if urine output continues. If the serum [K⁺] is greater than 7 mEq/L or if potentiating factors such as hyponatremia, digitalis toxicity, and renal failure are present, more aggressive therapy is needed (Table 23–10).

Table 23–10. Drugs for the Treatment of Hyperkalemia in Children.

<table>
<thead>
<tr>
<th>Drug</th>
<th>Dose</th>
<th>Actions</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>Calcium gluconate (10% solution)</td>
<td>0.2–0.5 mL/Kg IV given over 2–10 min (maximum dose 20 mL)</td>
<td>Cardiac membrane stabilization. Does not alter the serum K⁺ level.</td>
<td>Cardiac monitoring needed. May repeat dose if EKG changes persist. Discontinue if bradycardia develops.</td>
</tr>
<tr>
<td>Sodium polystyrene sulfonate</td>
<td>1 g/kg oral every 6 h or rectal every 2–6 h.</td>
<td>Ion exchange resin that exchanges K⁺ for Na⁺. Will decrease total body K⁺.</td>
<td>Do not use in neonates and patients with bowel hypomotility or bowel obstruction due to risk of intestinal necrosis. May cause hypernatremia, hypocalemia, and hypomagnesemia.</td>
</tr>
<tr>
<td>Sodium bicarbonate</td>
<td>1 mEq/kg (maximum dose 50 mEq).</td>
<td>Transient shift of K⁺ from the ECF to the ICF compartment.</td>
<td>Avoid use if alkalois or hypocalemia is present. May cause hypernatremia, hypocalemia.</td>
</tr>
<tr>
<td>Furosemide</td>
<td>1–2 mg/kg IV.</td>
<td>Diuretic that increases renal K⁺ excretion. Will decrease total body K⁺.</td>
<td>May need higher doses in patients with chronic kidney disease to achieve desired effect.</td>
</tr>
<tr>
<td>Albuterol (nebulized)</td>
<td>Infants and children &lt; 5 years of age: 2.5 mg in 2 mL of saline. Children &gt; 5 years of age: 5 mg in 2 mL of saline Adolescents: 10 mg in 2 mL of saline.</td>
<td>Transient shift of K⁺ from the ECF to the ICF compartment.</td>
<td>May repeat for 1 additional dose. Tachycardia may limit repeat dosing.</td>
</tr>
<tr>
<td>Insulin (regular)</td>
<td>Glucose 0.5–1 g/kg with 0.3 units of insulin per gram of glucose given over 2 h.</td>
<td>Transient shift of K⁺ from the ECF to the ICF compartment.</td>
<td>Must be given with a glucose infusion to prevent severe hypoglycemia. Diabetic patients may not require glucose infusion. Requires close monitoring of serum glucose.</td>
</tr>
</tbody>
</table>
If electrocardiographic changes or arrhythmias are present, treatment must be initiated promptly. Intravenous calcium gluconate will rapidly ameliorate depolarization and may be repeated after 5 minutes if electrocardiographic changes persist. Calcium should be given only with a cardiac monitor in place and should be discontinued if bradycardia develops. The intravenous administration of a diuretic that acts in the loop of Henle, such as furosemide, will augment renal K+ excretion and can be very helpful in lowering serum and total body [K+]. Administering Na+ and increasing systemic pH with bicarbonate therapy will shift K+ from the ECF to the ICF compartment, as will therapy with a β-agonist such as albuterol. In nondiabetic patients, 0.5 g/kg of glucose over 1–2 hours will enhance endogenous insulin secretion, lowering serum [K+] to 1–2 mEq/L. Administration of intravenous glucose and insulin may be needed as a simultaneous drip persist. Calcium should be given only with a cardiac monitor be repeated after 5 minutes if electrocardiographic changes or other bicarbonate-rich gastrointestinal losses suggests the possibility of renal tubular acidosis and should be evaluated appropriately (see Chapter 24). In contrast, acidosis that results from the addition of an unmeasured acid is associated with a widened anion gap. Examples are diabetic ketoacidosis, lactic acidosis, starvation, uremia, toxin ingestion (salicylates, ethylene glycol, or methanol), and certain inborn errors of organic or amino acid metabolism. Thus, a normal anion gap acidosis in the absence of diarrhea or other bicarbonate-rich gastrointestinal losses suggests the possibility of renal tubular acidosis and should be evaluated appropriately.

**ACID-BASE DISTURBANCES**

When evaluating a disturbance in acid-base balance, the systemic pH, partial carbon dioxide pressure (PCO₂), serum HCO₃⁻, and anion gap must be considered. The anion gap, [Na⁺ – (Cl⁻ + HCO₃⁻)], is an expression of the unmeasured anions in the plasma and is normally 12 ± 4 mEq/L. An increase above normal suggests the presence of an unmeasured anion, such as occurs in diabetic ketoacidosis, lactic acidosis, and salicylate intoxication. Although the base excess (or deficit) is also used clinically, it is important to recall that this expression of acid-base balance is influenced by the renal response to respiratory disorders and cannot be interpreted independently (as in a compensated respiratory acidosis, wherein the base excess may be quite large).

**METABOLIC ACIDOSIS**

Metabolic acidosis is characterized by a primary decrease in serum [HCO₃⁻] and systemic pH due to the loss of HCO₃⁻ from the kidneys or gastrointestinal tract, the addition of an acid (from external sources or via altered metabolic processes), or the rapid dilution of the ECF with nonbicarbonate-containing solution (usually normal saline). When HCO₃⁻ is lost through the kidneys or gastrointestinal tract, Cl⁻ must be reabsorbed with Na⁺ disproportionately, resulting in a hyperchloremic acidosis with a normal anion gap. Thus, a normal anion gap acidosis in the absence of diarrhea or other bicarbonate-rich gastrointestinal losses suggests the possibility of renal tubular acidosis and should be evaluated appropriately.

The ingestion of unknown toxins or the possibility of an inborn error of metabolism (see Chapter 36) must be considered in children without an obvious cause for a widened anion gap acidosis. Unfortunately, some hospital laboratories fail to include ethylene glycol or methanol in their standard toxicology screens, so assay of these toxins must be requested specifically. This is of critical importance when therapy with fomepizole (4-methylpyrazole) must be considered for either ingestion—and instituted promptly to obviate profound toxicity. Ethylene glycol (eg, antifreeze) is particularly worrisome because of its sweet taste and accounts for a significant number of toxin ingestions. Screening by fluorescence of urine under a Wood lamp is relatively simple but does not replace specific laboratory assessment. Salicylate intoxication has a stimulatory effect on the respiratory center of the CNS; thus, patients may initially present...
with respiratory alkalosis or mixed respiratory alkalosis and widened anion gap acidosis.

Most types of metabolic acidosis will resolve with correction of the underlying disorder, improved renal perfusion, and acid excretion. Intravenous NaHCO$_3$ administration may be considered in the setting of metabolic acidosis when the pH is less than 7.0 or the [HCO$_3^-$] is less than 5 mEq/L, but only if adequate ventilation is ensured. The dose (in milliequivalents) of NaHCO$_3$ may be calculated as:

\[
\text{Weight (kg)} \times \text{Base deficit} \times 0.3
\]

and given as a continuous infusion over 1 hour. The effect of NaHCO$_3$ in lowering serum potassium and ionized calcium concentrations must also be considered and monitored.

**METABOLIC ALKALOSIS**

Metabolic alkalosis is characterized by a primary increase in [HCO$_3^-$] and pH resulting from a loss of strong acid or gain of buffer base. The most common cause for a metabolic alkalosis is the loss of gastric juice via nasogastric suction or vomiting. This results in a Cl$^-$-responsive alkalosis, characterized by a low urinary [Cl$^-$] (< 20 mEq/L) indicative of a volume-contracted state that will be responsive to the provision of adequate Cl$^-$ salt (usually in the form of normal saline). Cystic fibrosis may also be associated with a Cl$^-$-responsive alkalosis due to the high losses of NaCl through the sweat, whereas congenital Cl$^-$-losing diarrhea is a rare cause of Cl$^-$-responsive metabolic alkalosis. Chloride-resistant alkaloses are characterized by a urinary [Cl$^-$] greater than 20 mEq/L and include Bartter syndrome, Cushing syndrome, and primary hyperaldosteronism, conditions associated with primary increases in urinary [Cl$^-$], or volume-expanded states lacking stimuli for renal Cl$^-$ reabsorption. Thus, the urinary [Cl$^-$] is helpful in distinguishing the nature of a metabolic alkalosis, but must be specifically requested in many laboratories because it is not routinely included in urine electrolyte panels. The serum [K$^+$] is also low in these settings (hypokalemic metabolic alkalosis) owing to a combination of increased mineralocorticoid activity associated with volume contraction, the shift of K$^+$ to the ICF compartment, and preferential reabsorption of Na$^+$ rather than K$^+$ to preserve intravascular volume. A hypokalemic alkalosis seen in the setting of primary mineralocorticoid excess would be expected to be associated with systemic hypertension clinically, as observed in an adrenal adenoma and some forms of monogenic hypertension, including Liddle syndrome and apparent mineralocorticoid excess.

**RESPIRATORY ACIDOSIS**

Respiratory acidosis develops when alveolar ventilation is decreased, increasing Pco$_2$, and lowering systemic pH. The kidneys compensate for respiratory acidosis by increasing HCO$_3^-$ reabsorption, a process that takes several days to fully manifest. Patients with acute respiratory acidosis frequently demonstrate air hunger with retractions and the use of accessory respiratory muscles. Respiratory acidosis occurs in upper or lower airway obstruction, ventilation-perfusion disturbances, CNS depression, and neuromuscular defects. Hypercapnia is not as detrimental as the hypoxia that usually accompanies these disorders. The goal of therapy is to correct or compensate for the underlying pathologic process to improve alveolar ventilation. Bicarbonate therapy is not indicated in a pure respiratory acidosis, because it will worsen the acidosis by shifting the equilibrium of the carbonic acid–bicarbonate buffer system to increase Pco$_2$.

**RESPIRATORY ALKALOSIS**

Respiratory alkalosis occurs when hyperventilation results in a decrease in Pco$_2$, and an increase in systemic pH. Depending on the acuity of the respiratory alkalosis, there may be an associated compensatory loss of bicarbonate by the kidneys manifested as a low serum bicarbonate level and a normal anion gap that may be misinterpreted as a normal anion gap acidosis if all acid-base parameters are not considered. Patients may experience tingling, paresthesias, dizziness, palpitations, syncope, or even tetany and seizures due to the associated decrease in ionized calcium. Causes of respiratory alkalosis include psychobehavioral disturbances, CNS irritation from meningitis or encephalitis, salicylate intoxication, and iatrogenic over ventilation in patients who are mechanically ventilated. Therapy is directed toward the causal process. Rebreathing into a paper bag will decrease the severity of symptoms in acute hyperventilation.

Anomalies of the ears, eyes, or external genitalia may be associated with renal anomalies or disease. The blood pressure should be measured in a quiet setting in the right upper extremity. The cuff should cover two-thirds of the child’s upper arm, and peripheral pulses should be assessed. The abdomen should be palpated, with attention to nephromegaly, abdominal masses, musculature, and the presence of ascites.

**LABORATORY EVALUATION OF RENAL FUNCTION**

**Serum Analysis**

The standard indicators of renal function are serum levels of urea nitrogen and creatinine; their ratio is normally about 10:1. This ratio may increase when renal perfusion or urine flow is decreased, as in urinary tract obstruction or dehydration. Because serum urea nitrogen levels are more affected by these and other factors (e.g., nitrogen intake, catabolism, use of corticosteroids) than are creatinine levels, the most reliable single indicator of glomerular function is the serum level of creatinine. For example, an increase in serum creatinine from 0.5 to 1.0 mg/dL represents a 50% decrease in GFR (glomerular filtration rate). Norms for serum creatinine relate to muscle mass. Therefore, only larger adolescents should have levels exceeding 1 mg/dL. Serum cystatin C has been proposed to be a more reliable indicator of glomerular function but may be less widely available, with variable reference ranges in the pediatric population and invalid values observed in the setting of corticosteroid administration or thyroid disease. Less precise but nonetheless important indicators of possible renal disease are abnormalities of serum electrolytes, pH, calcium, phosphorus, magnesium, albumin, or complement.
Glomerular Filtration Rate

The endogenous creatinine clearance (CCr) in milliliters per minute estimates the GFR. A 24-hour urine collection is the “classic” approach for determining CCr; however, it is often difficult to accurately obtain in the pediatric population, particularly in children who are not continent. The procedure for collecting a timed urine specimen should be explained carefully so that the parent or patient understands fully the rationale of (1) first emptying the bladder (discarding that urine) and noting the time and (2) putting all urine subsequently voided into the collection receptacle, including the last void, 24 hours later. Reliability of the 24-hour collection can be assessed in individuals with normal muscle mass by measuring the total 24-hour creatinine excretion in the specimen. Total daily creatinine excretion (creatinine index) should be 15–25 mg/kg. Creatinine indices on either side of this range suggest collections that were either inadequate or excessive. Calculation by the following formula requires expression as mL/min:

\[
CCr = \frac{U_C \times V}{P_C}
\]

Because accepted ranges of normal CCr are based on adult parameters, correction for size is needed in children. Clearance is corrected to a standard body surface area of 1.73 m² in the formula:

“Corrected” CCr = \[
\frac{\text{Patient’s } CCr \times 1.73 \text{ m}^2}{\text{Patient’s body surface area}}
\]

As 80–125 mL/min/1.73 m² is the normal range for CCr, estimates at the lower end of this range may indicate problems.

A quick approximation of CCr based on plasma or serum creatinine level and length in centimeters can be obtained as follows:

\[
CCr(\text{mL/min/1.73 m}^2) = 0.413 \times \text{height (cm)/P_C(mg/dL)}
\]

This formula was developed in children with chronic renal insufficiency and likely underestimates GFR in children with normal renal function. When cystatin C (cysC) has been assessed, the following formula may be utilized to include this variable and blood urea nitrogen (BUN):

\[
CCr(\text{mL/min/1.73 m}^2) = 39.8 \times [\text{height (m)/P_C(mg/dL)}]^{0.456} \times (1.8/\text{cysC(mg/L)})^{0.418} \times [30/\text{BUN}]^{0.079} \times 1.076 \times \frac{\text{[ht(m)/1]}}{}
\]

This more extensive calculation may be useful as a confirmatory test in specific circumstances when eGFR based on serum creatinine is less accurate (eg, low muscle mass) or when the clinical scenario warrants a secondary test. Online tools can be utilized to facilitate this calculation.

Urine Concentrating Ability

Inability to concentrate urine causes polyuria, polydipsia, or enuresis and is often the first sign of chronic renal failure, and, in some cases, raises the possibility of diabetes insipidus. The first morning void should be concentrated (specific gravity ≥ 1.020), presuming cessation of fluid intake overnight. Thus, determination of the specific gravity of a first morning void is an easy and helpful test of the kidney’s concentrating ability.

Urinalysis

Commercially available dipsticks can be used to screen the urine for blood, leukocytes, nitrites, protein, and specific gravity and to approximate the urine pH. Positive results for blood should always be confirmed by microscopy, which is also the only way to determine if there is significant crystalluria or casts. Hematuria is present with >5 RBC/high-powered field (hpf). Significant proteinuria (≥ 30 mg/dL) detected by dipstick should be confirmed by quantitation, either with a 24-hour urine collection or by the protein/creatinine ratio of a random specimen.

In children with asymptomatic hematuria or proteinuria, the search for renal origins will yield the most results, although urologic etiologies require consideration. Urinary red blood cell (RBC) casts suggest glomerulonephritis (GN), but the absence of casts does not exclude this disease. Urine RBC morphology may be helpful, with dysmorphic RBC arising from the kidneys. Anatomic abnormalities such as cystic disease with cyst rupture may also cause hematuria. Benign hematuria, including benign familial hematuria/thin glomerular basement membrane disease, is diagnosed by exclusion. Hematuria can also be observed in the setting of hypercalciuria or urolithiasis. Note that hypercalciuria is not associated with proteinuria. Figure 24–1 suggests an approach to the renal workup of hematuria. GN is discussed in more detail later in this chapter.

Combined proteinuria and hematuria is characteristic of more significant glomerular disease. Quantification of proteinuria is customarily accomplished by a timed collection (eg, over a 24-hour period). However, given the frequency of errors in collection in the pediatric population and the potential difficulties in timed collection in children who are not toilet trained, the degree of proteinuria may be estimated by the ratio of protein (mg/dL)/creatinine (mg/dL) in a random urine sample. A urine protein/creatinine ratio above 0.2 is abnormal. If the laboratory reports this as mg protein per gram of creatinine, normal is 200 or less.
**CHAPTER 24**

**Initial Data**

*History*: recent acute infection  
*Family history*: dialysis, transplant, familial hematuria/nephritis, hearing loss  
*PE*: blood pressure, edema, rash, joint findings  
*Lab*: urinalysis—hematuria with ≥ 5 RBC/hpf, RBC casts, protein; urine protein creatinine ratio; urine calcium creatinine ratio; BUN, serum creatinine & albumin; cystatin C; anti-streptococcal antibodies; serum C3; other testing as clinically indicated (urine culture, ANA, anti-dsDNA, ANCA)  
*Imaging*: renal ultrasound

---

**Glomerulonephritis (GN):**  
- RBC casts, proteinuria, edema, hypertension, RUS with echogenic kidneys

**Isolated gross hematuria**  
- Consider mild GN, urolithiasis, hypercalciuria, UPJ obstruction (hydronephrosis), UTI, sickle cell trait, trauma

**Depressed serum C3**  
- Postinfectious GN (low C3 normalizes within 6 weeks)  
- Membranoproliferative GN/C3 glomerulopathy  
- Lupus nephritis (positive ANA, anti-dsDNA)  
- Shunt nephritis (rare)  
- Endocarditis-associated GN (rare)

**Normal serum C3**  
- IgA nephropathy  
- HSP nephritis  
- ANCA-mediated vasculitis  
- Alport syndrome  
- Other immune complex mediated GN

**Discolored urine with < 5 RBC/hpf**  
- Consider hemoglobinuria, myoglobinuria, drugs

**Isolated microhematuria**  
- Consider mild GN, hypercalciuria, UTI, sickle cell trait, trauma

▲ **Figure 24–1.** Approach to the evaluation of hematuria. ANA, antinuclear antibody; ANCA, antineutrophil cytoplasmic antibody; BUN, blood urea nitrogen; dsDNA, double-stranded DNA; C3, complement; hpf, high-power field; HSP, Henoch-Schönlein purpura; IgA, immunoglobulin A; RBC, red blood cell; RUS, renal ultrasound; UPJ, ureteropelvic junction; UTI, urinary tract infection.
In the evaluation of asymptomatic proteinuria, orthostatic or postural proteinuria should be excluded. This can be accomplished simply by comparing the protein/creatinine ratio of urine formed in the supine position (the first morning void accumulated in the bladder while sleeping) to a sample obtained during daily ambulation. If the "supine" sample is normal and proteinuria is occurring only during upright posture, this demonstrates postural proteinuria. Such patients typically show resolution of orthostatic proteinuria over time, but rarely an orthostatic pattern can be seen initially in GN, so ongoing follow-up is warranted. If both samples are abnormal, proteinuria would be considered "persistent."

An approach to the workup of isolated proteinuria, including nephrotic syndrome, is shown in Figure 24–2. The presence of significant hematuria (> 20 RBC/hpf) or RBC casts should raise concern for glomerulonephritis (see Figure 24–1). Note that corticosteroid therapy is included in the algorithm because this may be initiated for nephrotic syndrome prior to referral. Other renal lesions

![Figure 24–2. Approach to the workup of isolated proteinuria. Rule out benign postural proteinuria with urine protein/creatinine ratio of first morning void (recumbent urine) versus day void (upright). BP, blood pressure; Cr, creatinine; hpf, high-power field; RBC, red blood cell; U/A, urinalysis; VCUG, voiding cystourethrogram.](image-url)
with proteinuric manifestations are discussed later in this chapter.

**Special Tests of Renal Function**

Measurements of urinary sodium, creatinine, and osmolality are useful in differentiating prerenal from renal causes of acute kidney injury. The physiologic response to decreased renal perfusion is decreased urinary output, increased urine osmolality, increased urinary solute concentration (eg, creatinine), and decreased urinary sodium (usually < 20 mEq/L).

The presence of certain substances in urine may suggest tubular dysfunction. For example, urine glucose should be less than 5 mg/dL in the setting of normal serum glucose concentration. Hyperphosphaturia occurs with significant proximal tubular abnormalities (eg, Fanconi syndrome). Measurement of the phosphate concentration of a 24-hour urine specimen and evaluation of tubular reabsorption of phosphorus (TRP) will help document renal tubular diseases as well as hyperparathyroid states. TRP (expressed as percentage of reabsorption) is calculated as follows:

$$\text{TRP} = 100 \left(1 - \frac{S_{CO_2} \times U_{PO_4}}{S_{PO_4} \times U_{CO_2}}\right)$$

where $S_{CO_2}$ = serum creatinine, $U_{CO_2}$ = urine creatinine, $S_{PO_4}$ = serum phosphate, and $U_{PO_4}$ = urine phosphate. All values for creatinine and phosphate are expressed in milligrams per deciliter for purposes of calculation. A TRP value of 80% or more is considered normal, although it depends somewhat on the value of $S_{PO_4}$.

A quantitative increase in urinary excretion of amino acids is seen in generalized proximal tubular disease. Defective proximal tubular reabsorption of bicarbonate can be seen in isolated renal tubular acidosis (RTA), Fanconi syndrome, and chronic renal failure.

**LABORATORY EVALUATION OF IMMUNOLOGIC FUNCTION**

Many parenchymal renal diseases are thought to have immune causation, although the mechanisms are largely unknown. Examples include (1) deposition of circulating antigen-antibody complexes that are directly injurious or incite injurious responses and (2) formation of antibody-antigen-antibody complexes that are directly injurious or lead to immune causation, although the mechanisms are largely unknown. Examples include (1) deposition of circulating antigen-antibody complexes that are directly injurious or incite injurious responses and (2) formation of antibody-antigen-antibody complexes that are directly injurious or lead to immune causation.

Serum C3 and C4 complement concentrations should be measured when immune-mediated renal injury or chronic GN is suspected. Where clinically indicated, anti-nuclear antibodies, antineutrophil cytoplasmic antibodies, hepatitis B surface antigen, and hepatitis C antibody should be obtained. In rare cases, cryoglobulins (very rare in childhood), C3 nephritic factor and other assessment of complement function, or antiglomerular basement membrane (anti-GBM) antibody measurements may help confirm a specific diagnosis. At some point in the workup, the diagnosis may be supported or confirmed by histologic examination of renal tissue.

**RADIOGRAPHIC EVALUATION**

Renal ultrasonography is a useful noninvasive tool for evaluating renal parenchymal disease, urinary tract abnormalities, and renal blood flow. Radioisotope studies provide information about renal anatomy, blood flow, and integrity and function of the glomerular, tubular, and collecting systems. Renal stones are often visualized by ultrasonography but are best delineated by computed tomography (CT). Due to lack of radiation, ultrasonography is usually used for screening and follow-up of urolithiasis. Voiding cystourethrography is indicated when vesicoureteral reflux (VUR) or bladder outlet obstruction (eg, to visualize the posterior urethra) is suspected. Cystoscopy is rarely useful in the evaluation of asymptomatic hematuria or proteinuria in children. Abdominal magnetic resonance imaging (MRI) or CT are useful for the identification and delineation of renal or adrenal masses. Doppler ultrasound is helpful to exclude renal arterial or venous thrombosis but of variable sensitivity and specificity in the diagnosis of renal artery stenosis; the latter condition is better assessed by MR or CT angiography. Intrarenal arterial stenosis may require direct renal arteriography.

**RENAL BIOPSY**

Histologic information is valuable in select cases to diagnose, guide treatment, and inform prognosis. Satisfactory evaluation of renal tissue requires examination by light, immunofluorescence, and electron microscopy. The need for a renal biopsy should be determined by a pediatric nephrologist.

**CONGENITAL ANOMALIES OF THE URINARY TRACT**

About 10% of children have congenital anomalies of the genitourinary tract, which range in severity from asymptomatic to lethal. Recent findings suggest that congenital anomalies of the kidney and urinary tract (CAKUT) may arise from mutations in a multitude of different single gene causes. Some asymptomatic abnormalities may have significant implications. For example, patients with “horseshoe” kidney (kidneys fused in their lower poles), although very rarely associated with reduction in kidney function, have a higher incidence of renal calculi. Unilateral agenesis or multicystic dysplasia is usually accompanied by compensatory hypertrophy of the contralateral kidney and thus is typically
associated with normal renal function. Supernumerary and ectopic kidneys are often of no significance. Abnormal genitourinary tract development can be associated with varying degrees of renal dysplasia and dysfunction ranging from mild to severe; an example of the latter is in utero bilateral renal agenesis, which, without prenatal intervention to support lung development, is associated with oligohydramnios, abnormal facies and limb anomalies (eg, talipes equinovarus) from fetal compression, and perinatal death from pulmonary hypoplasia (Potter syndrome).

Renal Dysplasia

Renal dysplasia constitutes a spectrum of anomalies. In simple hypoplasia, which may be unilateral or bilateral, the affected kidneys are smaller than normal. In some forms of dysplasia, immature undifferentiated renal tissue persists. In some situations, the number of functional nephrons is insufficient to sustain normal renal function once the child reaches a critical body size. The lack of adequate renal tissue is not always readily discernible in the newborn period in the presence of normal or often increased urine production. Other forms of renal dysplasia include oligomeganephronia (characterized by the presence of only a few large glomeruli) and the cystic dysplasias (characterized by the presence of renal cysts). Simple renal cysts are rare in children and are typically observed in children with a history of significant chronic medical illness. The presence of multiple “simple” cysts should raise concern for possible underlying polycystic kidney disease.

Polycystic Kidney Disease

Both forms of polycystic kidney disease (autosomal dominant [ADPKD] or recessive [ARPKD]) are increasingly diagnosed by prenatal ultrasound. In its most severe form, ARPKD kidneys are dysfunctional in utero, and therefore newborns may demonstrate Potter sequence. In less severe cases, kidney enlargement by cysts may initially be recognized when nephromegaly is noted on physical examination. Hypertension is an early problem in ARPKD. The rate of progression of renal insufficiency varies in ARPKD, but many children with a neonatal renal presentation reach end-stage renal disease (ESRD) by school age. Recent studies suggest wide variation in phenotype, even within families. Some patients present in early adulthood with liver dysfunction from congenital hepatic fibrosis with moderate nephromegaly and mild to moderate chronic renal insufficiency.

With advances in radiographic imaging, ADPKD is being diagnosed earlier in life, including prenatally. Children with ADPKD can manifest many of the same findings as adults with ADPKD, such as enlarged kidneys, pain, hematuria, proteinuria, hypertension, kidney stones, and extrarenal cysts (pancreas, spleen, liver), although renal insufficiency and intracranial aneurysms are rare in childhood. Routine monitoring for hypertension is indicated in children with or known to be at-risk for ADPKD. Because cysts grow over time, a normal renal ultrasound does not exclude ADPKD in an at-risk child (ie, parent known to have ADPKD). Approximately half of patients with ADPKD reach ESRD by 60 years of age. Rarely ADPKD can present with Potter sequence or severe neonatal manifestations.

Medullary Cystic Disease/Nephronophthisis

Medullary cystic disease and nephronophthisis are inherited conditions with similar renal morphology characterized by bilateral small corticomedullary cysts in normal to small kidneys with tubulointerstitial scarring leading to ESRD. Numerous causative genes have been identified in nephronophthisis, all of which encode for proteins expressed in the primary cilia of renal epithelial cells, leading to classification as “ciliopathies.” Children with nephronophthisis manifest impaired urinary concentration leading to polyuria and polydipsia with progressive renal insufficiency in childhood or adolescence. Extrarenal involvement including retinitis pigmentosa, hepatic fibrosis, skeletal defects, cerebellar vermis aplasia, or other abnormalities can help target specific gene analysis. Several forms of autosomal dominant medullary cystic disease exist, usually presenting with adult-onset renal failure and no extrarenal involvement. However, uromodulin-associated kidney disease with hyperuricemia and renal failure can be seen in adolescents.

Obstructive Uropathy

Obstruction at the ureteropelvic junction may be the result of intrinsic muscle abnormalities, aberrant vessels, or fibrous bands. The lesion can cause hydroureter and usually presents as prenatal hydroureterosis, an abdominal mass in the newborn, or recurrent abdominal pain with vomiting in an older child (Dietl’s crisis). Obstruction can occur in other parts of the ureter, especially at the ureterovesical junction, causing proximal hydroureter and hydroureterosis. Renal radionuclide scan with furosemide “wash-out” will reveal or rule out obstruction as the cause of the hydroureterosis.
Whether intrinsic or extrinsic, urinary tract obstruction should be relieved as soon as possible to minimize damage to the kidneys.

Severe bladder malformations such as extrophy are clinically obvious and a surgical challenge. More subtle— but urgent in terms of diagnosis—is obstruction of urine flow from vestigial posterior urethral valves. This anomaly, which occurs almost exclusively in males, may be detected prenatally with an enlarged muscular bladder and hydronephrosis. Neonates may demonstrate a poor voiding stream or eventual UTI. The kidneys and bladder may be easily palpable. Leakage (ureteric perforation, although rare) proximal to the obstruction may produce urinary ascites. Decompression of the bladder is critical in children with posterior urethral valves to prevent irreversible kidney damage.

Prune belly (Eagle-Barrett) syndrome is an association of urinary tract anomalies with cryptorchidism and absent abdominal musculature. Renal dysplasia and/or functional urinary tract obstruction may lead to ESRD. Timely urinary diversion is essential to sustain renal function.

Other complex malformations and external genital anomalies are beyond the scope of this text. The challenge presented by urologic abnormalities resulting in severe compromise and destruction of renal tissue is to preserve all remaining renal function, prevent UTI, and treat the complications of progressive chronic renal failure. Collaboration between the pediatric urologist and nephrologist in early management is essential.

**Reflux Nephropathy**

The retrograde flow of urine from the bladder into the ureter (vesicoureteral reflux, VUR) may cause renal scarring and subsequent renal insufficiency or hypertension, or both, especially in the setting of UTIs. Hydronephrosis on renal ultrasound suggests the possibility of VUR or obstruction. VUR is diagnosed with a voiding cystourethrogram. Low-grade VUR typically resolves spontaneously over time. Prophylactic antibiotics may be administered depending on the child's age, degree of VUR, and frequency of UTI while awaiting spontaneous resolution. Surgery may be required for chronic severe reflux. Appropriate management of reflux nephropathy includes prevention and prompt treatment of UTI, monitoring and management of hypertension and complications of chronic renal insufficiency, and consideration of angiotensin-converting enzyme (ACE) inhibition to prevent glomerular hyperfiltration.

---

**HEMATURIA & GLOMERULAR DISEASE**

### MICROHEMATURIA

Children with painful hematuria should be investigated for UTI or direct injury to the urinary tract. Dysuria is common in cystitis or urethritis; associated back pain and/or fever suggests the possibility of pyelonephritis; and colicky flank pain may indicate the passage of a stone. Bright red blood or clots in the urine can also be associated with bleeding disorders, trauma, and arteriovenous malformations. Abdominal masses suggest the presence of urinary tract obstruction, cystic disease, or tumors of the renal or perirenal structures.

Asymptomatic hematuria is a challenge because clinical and diagnostic data are required to decide whether nephrology evaluation is needed. The diagnosis of hematuria should not rely solely on a urine “dipstick” evaluation, but it must be verified by a microscopic examination (normal < 5 RBC/hpf). Ruling out hypercalciuria as a cause of hematuria with a random urine calcium/creatinine ratio (both values in mg/dL) is one of the initial steps in the evaluation of hematuria. A value above 0.2 requires verification with a 24-hour urine collection when possible. Hypercalciuria is present with excretion of calcium in excess of 4 mg/kg/day. Figure 24–1 delineates the outpatient approach to renal hematuria. The primary concern in the differential diagnosis of hematuria is the possible presence of glomerular disease.

### GLOMERULONEPHRITIS

#### ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

**Classic features of glomerulonephritis:**

- Hematuria.
- Edema.
- Hypertension.
- Red blood cell casts in the urine.

The various types of glomerulonephritis (GN) have similar manifestations. Severe glomerular histopathologic and clinical entities, such as anti-GBM antibody disease (Goodpasture syndrome), granulomatosis with polyangiitis, and idiopathic, rapidly progressive GN, may be considered in the differential diagnosis of acute GN, but these disorders are unusual in children.

The defining features of GN include hematuria, urinary RBC casts, hypertension, and edema. Hematuria may be microscopic or gross (often coffee- or tea-colored) in nature.
While RBC casts are often present, their absence does not exclude the diagnosis of GN. Urine protein excretion may range from normal to nephrotic range. Edema (periorbital, facial, extremities, ascites) occurs due to salt and water retention with impaired glomerular function and contributes to systemic hypertension, which is further exacerbated by the glomerular inflammation and associated renin production. Therefore, diuretics followed by blockade of the renin-angiotensin-aldosterone system are the pillars of hypertension management. Affected children require evaluation of blood pressure, renal function, serum albumin, and urine protein excretion. Serum C3 concentration is helpful to distinguish certain types of AGN (depressed in postinfectious and membranoproliferative/C3GN, GN due to SLE, and GN related to ventriculoatrial shunt infection or endocarditis [the latter two conditions are rarely seen in childhood but typically evident by history and examination]). Renal biopsy may be indicated when the etiology of GN is not otherwise clear from history and preliminary testing.

**Acute Postinfectious Glomerulonephritis**

The diagnosis of acute poststreptococcal GN is supported by a recent history (typically within the preceding 7–14 days, with range of 1 day to 6 weeks) of group A β-hemolytic streptococcal infection, usually as pharyngitis or, less commonly, impetigo. If a positive culture is not available, recent infection may be supported by an elevated titer of antistreptococcal antibodies. However, documentation of elevated antistreptococcal antibodies alone does not confirm that GN is poststreptococcal in nature. Other infections can cause similar glomerular injury; thus “postinfectious” GN may be a preferred term for this type of acute glomerulonephritis (AGN). Postinfectious GN is associated with depressed serum C3 complement. The manifestations range from asymptomatic microhematuria to gross hematuria with nephrotic range proteinuria and renal insufficiency. However, in most cases, full recovery occurs and is usually complete within weeks.

Typical postinfectious GN has no specific treatment. Antibiotic therapy is indicated if an active infection is documented. Disturbances in renal function and resulting hypertension may require close monitoring, reduction in salt intake, diuretics, or other antihypertensive drugs such as ACE inhibitors. In cases of severe renal failure, hemodialysis or peritoneal dialysis may be necessary. Corticosteroids may also be administered in an attempt to influence the course of severe GN. Serum C3 may normalize as early as 24 hours or as late as 6 weeks after onset. In postinfectious GN, microscopic hematuria may persist for as long as a year; 85% of children recover completely. Persistent deterioration in renal function, chronic proteinuria, and presentation complicated by nephrotic syndrome are concerning signs for long-term prognosis.

**IgA Nephropathy**

When asymptomatic gross hematuria with or without proteinuria occurs concurrently with a minor acute illness or other stressful occurrence, the diagnosis of IgA nephropathy may be entertained. IgA nephropathy is the most common cause of GN. Serum complement is normal in this condition. IgA nephropathy may be accompanied by flank pain or dysuria. Gross hematuria typically resolves within days, and there are no serious sequelae in 85% of children. Treatment is not generally indicated, and the prognosis is good in most cases. Prognosis is guarded, however, if severe proteinuria, hypertension, or renal insufficiency is present or develops. In such instances, although no treatment is universally accepted, corticosteroids and other immunosuppressive drugs are used. Omega-3 fatty acids from fish oils are also thought to be helpful by inhibiting macrophage infiltration of the glomerular mesangium.

**Henoch-Schönlein Purpura**

The diagnosis of Henoch-Schönlein purpura (HSP) rests on the presence of a typical maculopapular and purpuric rash found primarily, but not exclusively, on the dorsal surfaces of the lower extremities and buttocks. Many children have abdominal pain, and bloody diarrhea may be present. Joint pain and swelling are common. Hypertension may be present. Kidney biopsy is rarely required due to the constellation of clinical findings, but lupus and ANCA-mediated vasculitis should be considered in the appropriate setting, particularly in adolescents. The renal histologic lesion of HSP is identical to that of IgA nephropathy. The condition is usually self-limited. Joint and abdominal pain responds to treatment with short courses of corticosteroids. Renal involvement ranges from none to mild GN with microhematuria to severe GN with associated nephrosis and renal insufficiency. More severe renal involvement is associated with worse long-term prognosis, including potential for progression to ESRD. There is no universally accepted treatment, but corticosteroids and other immunosuppressive agents are often administered (see Chapter 30).

**Membranoproliferative Glomerulonephritis/C3 Glomerulopathy**

The most common “chronic” form of GN in childhood is membranoproliferative GN. The diagnosis is established from the histologic appearance of the glomeruli on biopsy. Recent studies have led to reclassification of these conditions, recognizing that abnormalities of complement regulation may be the primary etiology. There is a wide phenotypic spectrum of these conditions. These conditions typically are associated with depressed serum C3.
Immunosuppressive treatment is recommended but response may vary depending on the underlying etiology.

**Lupus Glomerulonephritis**

The diagnosis of systemic lupus erythematosus (SLE) is based on its numerous clinical features and abnormal laboratory findings that include a positive antinuclear antibody test, depressed serum complement, and increased serum antibodies to double-stranded DNA. Renal involvement is indicated by varying degrees of hematuria and proteinuria. More severe cases are accompanied by renal insufficiency and hypertension. Significant renal involvement requires treatment with various combinations of immunosuppressive drugs including prednisone (as a primary drug), azathioprine, cyclophosphamide, mycophenolate, tacrolimus, and rituximab, a monoclonal antibody against the B-cell surface antigen CD20. ESRD develops in 10%–15% of patients with childhood SLE.

**Hereditary Glomerulonephritis**

The most commonly encountered hereditary GN is Alport syndrome. This condition is due to mutations in type IV collagen found in basement membranes of the glomeruli, cochlea, and lens, and is characterized by progressive GN, high-frequency sensorineural hearing loss, and lens abnormalities. Although the condition can be inherited in autosomal dominant or recessive manners, the vast majority of cases are X-linked in transmission. Thus, males are typically more severely affected. Such boys present very early in life, even in infant and toddler years, with persistent microhematuria and recurrent gross hematuria associated with intercurrent illness, followed by chronic proteinuria and then deterioration in renal function. A family history may be present, but there is a spontaneous mutation rate of about 20%. In males with X-linked or children with autosomal recessive disease, ESRD usually occurs in the second to third decade of life. Females with X-linked Alport syndrome show a wide spectrum of disease manifestation from asymptomatic hematuria to ESRD. Although currently there is no treatment for this disorder, careful management of associated hypertension may slow the process. A clinical trial in progress to evaluate the effect of ACE inhibitors to decrease transglomerular pressure in the setting of the genetically weakened glomerular basement membrane and thus preserve glomerular function.

**TUBULOINTERSTITIAL DISEASE**

**ACUTE INTERSTITIAL NEPHRITIS**

Acute interstitial nephritis is characterized by diffuse or focal inflammation and edema of the renal interstitium and secondary involvement of the tubules. The condition is most commonly drug related (eg, β-lactam–containing antibiotics or nonsteroidal anti-inflammatory drugs [NSAIDs]), but infectious etiologies, including Epstein-Barr virus, also occur. Fever, rash, and eosinophilia may occur in drug-associated cases. Urinalysis usually reveals leukocyturia and mild hematuria and proteinuria. Hansel staining of the urinary sediment may demonstrate eosinophils. The inflammation can cause significant deterioration of renal function and systemic hypertension. The association between tubulointerstitial nephritis and uveitis (TINU) is occasionally seen in childhood. If the diagnosis is unclear because of the absence of a history of drug or toxin exposure or acute infection, or the absence of eosinophils in the urine, a renal biopsy may be performed to demonstrate the characteristic tubular and interstitial inflammation. Immediate identification and removal of the causative agent whenever possible is imperative and may be all that is necessary. Treatment with corticosteroids is helpful in patients with progressive renal insufficiency or associated nephrotic syndrome. Dialysis support is occasionally required.

**PROTEINURIA & RENAL DISEASE**

Urine is rarely completely protein free, but the average excretion is well below 150 mg/24 h. As noted previously, small increases in urinary protein can accompany febrile illnesses or exertion and in some cases occur while in the upright posture (orthostatic proteinuria).

An algorithm for investigation of isolated proteinuria is presented in Figure 24–2. In idiopathic nephrotic syndrome without associated features of GN, treatment with corticosteroids may be initiated. Nephrologic advice or follow-up should be sought, especially in patients with high-grade or frequently relapsing proteinuria.
CONGENITAL NEPHROSIS (FINNISH TYPE)

Congenital nephrosis of the Finnish type is a rare autosomal recessive disorder characterized by microcystic dilations of the proximal tubules and glomerular abnormalities including proliferation, crescent formation, and thickening of capillary walls. The condition is associated with genetic mutations in NPHS1.

Infants with congenital nephrosis commonly have markedly elevated maternal serum α-fetoprotein concentration, a large placenta, wide cranial sutures, and delayed ossification. Progressive edema may be seen after the first few weeks of life. Massive urine protein losses lead to other risks including recurrent infection due to hypogammaglobulinemia (urinary loss of immunoglobulin G), thrombosis (urinary loss of antithrombin III), and eventual clinical hypothyroidism (urinary loss of thyroid-binding globulin). Such children usually require nightly high-dose albumin infusions and once to twice weekly intravenous immunoglobulin (IVIG) infusions. Nephrectomies may be required to prevent complications of the high-grade protein losses. Progressive renal failure requiring dialysis and transplantation are anticipated, although historically affected infants often succumbed to serious bacterial infection in the first year of life.

IDIOPATHIC NEPHROTIC SYNDROME OF CHILDHOOD

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

Classic features of nephrotic syndrome

- Proteinuria.
- Hypoalbuminemia.
- Edema.
- Hyperlipidemia.

Clinical Findings

Affected patients are generally younger than 6 years at onset. Typically, periorbital swelling and oliguria are noted, often following intercurrent illness. Within a few days, increasing edema—even anasarca—becomes evident. Most children have few complaints other than vague malaise or abdominal pain. With significant hypoalbuminemia, some children experience symptoms of intestinal malabsorption. With marked edema, dyspnea due to pleural effusions or massive ascites may also occur.

Despite heavy proteinuria, the urine sediment is usually normal, although microscopic hematuria may be present. Gross hematuria is occasionally seen but more often with FSGS than minimal change disease (MCD). Plasma albumin concentration is low and lipid levels increased. When azotemia occurs, it is usually secondary to intravascular volume depletion from “third space” leak and low oncotic pressure.

Complications

Infections (eg, peritonitis, sepsis) sometimes occur, and Streptococcus pneumoniae is frequently the cause. Hypercoagulability may be present, and thromboembolic phenomena such as deep venous thrombosis, renal vein thrombosis or sagittal sinus thrombosis are reported. Hypertension can occur, and renal insufficiency can result from decreased renal perfusion. Hyperlipidemia resolves when affected children enter remission but is of concern in treatment-resistant nephrotic syndrome.

Treatment & Prognosis

When the diagnosis of idiopathic nephrotic syndrome is made, corticosteroid treatment should be started as the vast majority of children will enter remission in response to such treatment, thus avoiding the need for kidney biopsy that neither predicts response to treatment nor long-term renal function. Prednisone, 2 mg/kg/day (maximum, 60 mg/day), is given for 6 weeks as a single daily dose. The same dose is then administered on an alternate-day schedule for 6 weeks. Thereafter, the corticosteroids are discontinued or the dose tapered gradually and discontinued over the ensuing few months depending on local practice. The goal of this regimen is the disappearance of proteinuria. If remission is not achieved during the initial 4 weeks of corticosteroid treatment, nephrologic consultation is needed. If remission is achieved, only to be followed by relapse, the treatment course may be repeated. A renal biopsy is often considered when there is little or no response to treatment. One should take into account, however, that the histologic findings may not necessarily alter the treatment plan, which is designed to eliminate the nephrotic syndrome regardless of underlying renal histology.

Careful clinical assessment of intravascular volume status is indicated to guide diuretic therapy in children with idiopathic nephrotic syndrome. While those with obvious evidence of volume overload will benefit from diuretics, some children, particularly those with MCD, will show evidence of intravascular volume depletion due to third space fluid leak. The latter group of children will experience hypotension and prerenal azotemia with aggressive diuresis; thus, careful restoration of compromised circulating volume with intravenous 25% albumin infusion with consideration of a diuretic such as furosemide is most helpful in mobilizing edema. Infections such as peritonitis should be treated promptly to reduce morbidity. Immunization with pneumococcal conjugate and polysaccharide vaccines is advised due to the increased risk of invasive pneumococcal disease with active relapse.
Resolution of proteinuria with corticosteroid treatment suggests a good prognosis. Early relapse usually heralds a prolonged series of relapses; frequent relapses increase corticosteroid exposure and should lead to consideration of alternate immunosuppressive therapy to maintain remission. Historically, chlorambucil or cyclophosphamide were added to corticosteroid treatment in steroid-responsive but dependent children to achieve corticosteroid discontinuation while maintaining remission. Because of potential significant side effects associated with these drugs, tacrolimus or, less commonly, cyclosporine is now added instead in steroid-dependent cases. Children who fail to respond to corticosteroids have a more guarded long-term prognosis for renal function yet may still attain remission with alternative immunosuppressive agents. Increasing reports and experience suggest that cases in which nephrotic syndrome is poorly responsive to or “dependent” upon corticosteroids, even with an added agent such as tacrolimus, may respond to rituximab, although no controlled trials have been conducted and the long-term effects of repeated courses of rituximab in this setting are not known. Patients who do not respond to corticosteroids or who relapse frequently should be referred to a pediatric nephrologist, if such referral was not made earlier in the course.

FOCAL SEGMENTAL GLOMERULOSCLEROSIS

Focal segmental glomerulosclerosis (FSGS) is a cause of idiopathic nephrotic syndrome in children but can also cause chronic asymptomatic proteinuria. The condition is concerning as up to 15%–20% of cases can progress to end-stage renal failure. The response to corticosteroid treatment is variable. Treatment in the setting of active nephrotic syndrome is reviewed above, but the benefits of chronic immunosuppressive therapy are less clear in the asymptomatic child. Recurrence of FSGS is common following renal transplantation. Fortunately, most children respond well to treatment with plasmapheresis and/or rituximab; the latter agent is also showing encouraging utility in treating the nephrotic syndrome of membranous or mesangial nephropathy as well as refractory nephrotic syndrome associated with other forms of glomerular disease or vasculitis.

MEMBRANOUS NEPHROPATHY (MEMBRANOUS GLomerulonePHRITIS)

Although largely idiopathic in nature, membranous nephropathy can be found in association with infections, including hepatitis B, hepatitis C, and congenital syphilis; with immunologic disorders such as autoimmune thyroiditis and SLE (in contrast to other forms of lupus nephritis, serum C3 is often normal with membranous lupus); and with administration of drugs such as penicillamine. Recent studies suggest a high frequency of antibodies to podocyte antigens in affected patients.

The onset of membranous nephropathy may be insidious or may resemble that of idiopathic nephrotic syndrome of childhood (see earlier section). It occurs more often in older children and adults. The proteinuria of membranous nephropathy may respond poorly to corticosteroid therapy, although low-dose corticosteroid therapy may reduce or delay development of chronic renal insufficiency. The diagnosis is made by renal biopsy.

DISEASES OF THE RENAL VESSELS

RENAl VEIN THROMBOSIS

In newborns, renal vein thrombosis may complicate sepsis or dehydration. It may be observed in infants of diabetic mothers, may be associated with umbilical vein catheterization, or may result from any condition that produces a hypercoagulable state (eg, clotting factor deficiency, SLE, or thrombocytosis). Renal vein thrombosis is less common in older children and adolescents. It may develop following trauma, with a procoagulant state (such as antiphospholipid antibody positivity in SLE), or without any apparent predisposing factors. Spontaneous renal vein thrombosis has been associated with membranous nephropathy.

Clinical Findings

Renal vein thrombosis in newborns is generally characterized by the sudden development of an abdominal mass. If the thrombosis is bilateral, oliguria may be present. In older children, flank pain, sometimes with a palpable mass, is a common presentation.

No single laboratory test is diagnostic of renal vein thrombosis. Hematuria usually is present and may occasionally be gross in nature; proteinuria is less constant. In the newborn, thrombocytopenia may be found, but it is rare in older children. The diagnosis is made by ultrasonography and Doppler flow studies.

Treatment

Anticoagulation with heparin is the treatment of choice in newborns and older children. In the newborn, a course of heparin combined with treatment of the underlying problem
is usually all that is required; the risks of systemic anticoagulation in the newborn, particularly if preterm, must be considered. Evaluation for thrombophilia may be needed. In children with a known tendency for recurrence, more long-term anticoagulation may be required.

» Course & Prognosis

The mortality rate in newborns from renal vein thrombosis depends on the underlying cause. With unilateral renal venous thrombosis at any age, the prognosis for adequate renal function is good. Bilateral disease is of course more concerning, and long-term renal follow-up focusing on renal function and growth is warranted in such children. Renal vein thrombosis may rarely recur in the same kidney or in the other kidney years after the original episode of thrombus formation. Extension into the vena cava with pulmonary emboli is possible.

RENAL ARTERIAL DISEASE

Arterial disease (eg, fibromuscular dysplasia, congenital renal artery or midaortic stenosis, Takayasu arteritis) is a rare cause of hypertension in children. Although few clinical clues are specific to underlying arterial lesions, they should be suspected in children with severe hypertension, with onset at or before age 10 years, or in children who demonstrate increasingly difficult to control hypertension. The diagnosis is established by MR or CT angiography and confirmed by renal arteriography or direct intraoperative visualization. When vasculitis is present, immunosuppressive treatment is the first approach. Other lesions may be approached by transluminal angioplasty or surgery (see section Hypertension), but repair may be technically impossible in small children. In such cases, medical management of hypertension pending somatic growth is indicated. Although thrombosis of renal arteries is rare, it should be considered in a patient with acute onset of hypertension and hematuria in an appropriate setting (eg, in association with hyperviscosity or umbilical artery catheterization). Early diagnosis and treatment provides the best chance of reestablishing renal blood flow.

HEMOLYTIC-UREMIC SYNDROME

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

Classic Features of Hemolytic Uremic Syndrome

► Microangiopathic hemolytic anemia.
► Thrombocytopenia.
► Renal dysfunction.

Hemolytic-uremic syndrome is the most common glomerulovascular cause of acute renal failure in childhood. The diarrhea-associated form is usually the result of infection with Shiga toxin–producing strains of *Shigella* or *Escherichia coli*. Ingestion of under-cooked ground beef or unpasteurized foods is a common source. There are many serotypes, but the most common pathogen in the United States is *E. coli* O157:H7. Bloody diarrhea is the usual presenting complaint, followed by hemolysis, thrombocytopenia, and renal failure. Circulating toxin causes endothelial damage, which leads to platelet deposition/consumption and microvascular occlusion with subsequent hemolysis. Similar microvascular endothelial activation may also be triggered by drugs (eg, cyclosporin A); by viruses (human immunodeficiency virus [HIV]); and by pneumococcal infections, in which bacterial neuraminidase exposes the Thomsen-Friedenreich antigen on RBCs, platelets, and endothelial cells, with associated cell lysis. Rare cases are caused by genetic factors causing complement dysregulation (eg, factor H deficiency).

» Clinical Findings

Hemolytic-uremic syndrome (HUS) due to *Shigella* or *E. coli* begins with a prodrome of abdominal pain, diarrhea, and vomiting. Oliguria, pallor, and bleeding manifestations, principally gastrointestinal, occur next. Children with pneumococcal-associated HUS typically have documented pneumococcal pneumonia, sepsis, or meningitis. Children with atypical HUS associated with complement dysregulation often develop an episode of HUS following intercurrent illness and present with malaise and pallor. Hypertension and seizures develop in some children—especially those who develop severe renal failure and fluid overload. There may also be significant endothelial involvement in the central nervous system (CNS), heart, and pancreas. Anemia may be profound, and RBC fragments are seen on blood smears. A high reticulocyte count confirms the hemolytic nature of the anemia but may not be noted in the presence of renal failure. Thrombocytopenia is often severe, but other coagulation abnormalities are less consistent. Serum fibrin split products are often present, but fulminant disseminated intravascular coagulation is rare. Hematuria and proteinuria are often present. Hemoglobinuria is occasionally observed due to marked RBC hemolysis.

» Complications

Complications of acute kidney injury occur. Neurologic problems, particularly seizures, may result from hyponatremia, hypertension, or CNS vascular disease. Despite thrombocytopenia, many children are prone to thrombosis due to the underlying endothelial damage.
Treatment

Meticulous attention to fluid and electrolyte status is crucial. The use of antimitility agents and antibiotics for HUS caused by gastrointestinal infection is believed to worsen the disease. Antibiotics may upregulate and increase the release of large amounts of bacterial Shiga toxin. Timely dialysis improves the prognosis. Platelet inhibitors have also been tried, but the overall results have not been impressive, especially late in the disease. RBC transfusions are often necessary. Platelet transfusions should be avoided unless there is active bleeding. Erythropoietin (epoetin alfa) treatment may reduce RBC transfusion needs and is indicated in the setting of renal failure. Atypical HUS due to complement dysregulation may benefit from plasmapheresis or plasma infusion (by replacing missing factors or removing factor H autoantibodies), but these therapies have been more recently replaced by the anti-C5a monoclonal antibody, eculizumab. Whether eculizumab may be of benefit in other forms of HUS remains to be determined. Plasma therapy should be avoided in pneumococcal HUS as it provides the patient with anti–Thomsen-Friedenreich antibody and thereby drives the HUS process. Although no therapy is universally accepted, strict control of hypertension and fluid balance, adequate nutrition support, and the timely use of dialysis reduce morbidity and mortality. If renal failure is nonoliguric and if urine output is sufficient to ensure against fluid overload and electrolyte abnormalities, management of renal failure without dialysis is possible.

Course & Prognosis

Most commonly, children recover from the acute episode within 2–3 weeks. Some residual renal disease (including hypertension, proteinuria, or chronic renal insufficiency) occurs in about 30%, and end-stage renal failure occurs in about 15%. The risk of ESRD is higher in children with atypical or pneumococcal-induced HUS. Follow-up of children recovering from hemolytic-uremic syndrome should include serial determinations of renal function with frequency dictated by the etiology, course, and subsequent findings and routine monitoring of blood pressure. Overall mortality (about 3%–5%) is most likely in the early phase, primarily resulting from CNS or cardiac complications. As with most renal conditions, chronic proteinuria, hypertension, or abnormal renal function are associated with worse long-term renal prognosis and require judicious follow-up.

ACUTE KIDNEY INJURY

The term “acute kidney injury” denotes the sudden inability to excrete urine of sufficient quantity or composition to maintain body fluid homeostasis. Explanations include quickly reversible problems such as dehydration or urinary tract obstruction, as well as new-onset renal disease (eg, AGN), drug-related toxic nephropathies, or renal ischemia; the latter is primarily suspected in settings of significant hemodynamic instability or other circumstances resulting in decreased renal perfusion. Table 24–1 lists prerenal, renal, and postrenal causes of acute kidney injury.

Clinical Findings

The hallmark of early acute kidney injury is oliguria with subsequent variable rise in serum creatinine and BUN; these observations are more likely to be the initial concern in a hospitalized patient. Although an exact etiologic diagnosis may be unclear at the onset, classifying acute kidney injury

Note: Any of the prerenal etiologies of renal failure can evolve into acute tubular nephropathy when prolonged.

as outlined in Table 24–1 is helpful in determining if an immediately reversible cause is present.

Entities that can be quickly addressed and corrected, for example, intravascular volume depletion or urinary tract obstruction, should be considered first. Once normal renal perfusion and lack of urinary tract obstruction is ensured, if there is no clinical evidence for de novo renal disease, a diagnosis of acute tubular necrosis may be entertained.

**A. Prerenal Causes**

The most common cause of acute decreased renal function in children is compromised renal perfusion. It is usually secondary to true intravascular volume depletion or a decrease in effective circulating volume, as may be seen in cardiac failure, cirrhosis, or nephrotic syndrome. Table 24–2 lists the urinary indices helpful in distinguishing these “prerenal” conditions from true renal parenchymal insult, such as acute tubular necrosis.

**B. Renal Causes**

Causes of acute kidney injury intrinsic to the kidneys include acute glomerulonephritides, HUS, acute interstitial nephritis, and nephrotoxic injury. The diagnosis of acute tubular necrosis, which is reserved for those cases in which renal ischemic insult is believed to be the likely cause, should be considered when correction of prerenal or postrenal problems does not improve renal function and there is no evidence of de novo renal disease.

**C. Postrenal Causes**

Postrenal failure, usually found in newborns with urologic anatomic abnormalities, is accompanied by varying degrees of renal insufficiency. One should always keep in mind the possibility of acute urinary tract obstruction in acute kidney injury, especially in the setting of anuria of acute onset. Whatever the cause, ensuring urine drainage is the first step toward reversibility of oliguria.

**Complications**

The severity of the complications of acute kidney injury depends on the degree of renal functional impairment and oliguria. Common complications include (1) fluid overload (hypertension, congestive heart failure, and pulmonary edema), (2) electrolyte disturbances (hyperkalemia), (3) metabolic acidosis, (4) hyperphosphatemia, and (5) uremia.

**Treatment**

Prerenal and/or postrenal factors should be excluded and rectified. Normal circulating volume should be maintained and normal blood pressure and cardiac performance established with appropriate fluid or pressor support. Strict measurement of input and output must be maintained, with input adjusted as reduction in output dictates. Placement of a Foley bladder catheter can aid in timely measurement of the output. However, in cases where oligo/anuric renal failure is well established (ie, insignificant urine volume), the foreign body should be removed to minimize bladder infection risk. Measurement of central venous pressure may be indicated. Routine assessment of weight is helpful to assess fluid balance in children in whom this is possible. Increasing urine output with diuretics, such as furosemide (1–5 mg/kg, per dose, intravenously; maximum of 200 mg every 6 hours), can be attempted. The effective dose will depend on the amount of functional compromise (if < 50% function, initiate attempt at diuresis with maximum dose). If a response does not occur within 1 hour and the urine output remains low (< 0.5 mL/kg/h), the furosemide dose, if not already maximized, should be increased up to 5 mg/kg. In some cases, the addition of a long-acting thiazide diuretic, such as metolazone, may improve the response. If no diuresis occurs with maximum dosing, further administration of diuretics should cease and fluid intake should be restricted accordingly. The child should be monitored closely for indications for acute dialysis.

All medication dosages should be adjusted as appropriate for the degree of renal clearance.

**A. Acute Dialysis: Indications**

Immediate indications for dialysis are (1) hyperkalemia refractory to medical management; (2) unrelenting metabolic acidosis (usually in a situation where fluid overload or hypervolemia prevent repeated sodium bicarbonate administration); (3) fluid overload (which may be manifest as significant hypertension, congestive heart failure, pulmonary edema, or simply inability to provide appropriate medication and...
nutritional support due to fluid restriction); and (4) symptoms of uremia, usually manifested in children by CNS depression (rare). In cases in which one is concerned about the so-called “uremic” bleeding, it is important to keep in mind that despite the use of the clinical term uremia, it is not the blood urea nitrogen which contributes to platelet dysfunction in renal failure. Accumulation of metabolic end products that contribute to bleeding correlates better with the degree of renal function as reflected by the serum creatinine. This is especially true in cases in which the BUN, which is potentially affected by many things in an ill patient, appears to be disproportionately elevated with respect to the serum creatinine.

**B. Methods of Dialysis**

Peritoneal dialysis is often preferred in children because of ease of performance and patient tolerance. Although peritoneal dialysis is technically less efficient than hemodialysis, hemodynamic stability and metabolic control can be better sustained because this technique can be applied on a relatively continuous basis. Hemodialysis should be considered (1) if rapid removal of toxins is desired, (2) if the hemodynamic status will tolerate the intermittent solute and fluid removal, or (3) if impediments to efficient peritoneal dialysis are present (eg, postoperative abdomen, adhesions). If vascular access and potential usage of anticoagulation are not impediments, a slow, continuous hemodialytic process, continuous renal replacement therapy (CRRT), may be applied in hemodynamically unstable, critically ill patients, including those on extracorporeal membrane oxygenation. Typically, either systemic or regional anticoagulation is provided to maintain the extracorporeal circuit. Nutritional support and medication doses should be reviewed and adjusted accordingly for patients receiving dialytic therapies.

**C. Dialysis Management and Complications**

Intravascular volume depletion can be observed in any dialytic therapy; thus close attention to the patient’s hemodynamic status with adjustment in dialytic fluid removal is indicated. Significant intravascular volume depletion can contribute to acute tubular nephropathy and limit the timely recovery of intrinsic renal function. Complications specific to peritoneal dialysis include peritonitis and technical complications such as dialysate leakage or respiratory compromise from intra-abdominal dialysate fluid. Peritonitis risk can be diminished by strict aseptic technique. Peritoneal fluid cultures should be obtained as clinically indicated. Leakage is reduced by good catheter placement technique and appropriate intra-abdominal dialysate volumes. Adjustment of the electrolyte concentration of dialysate is important to maintain electrolyte balance. Potassium and phosphate, absent from standard dialysate solutions, can be added to the dialysate as clinically required. Several antibiotics can be added to the dialysate for intraperitoneal administration with associated systemic absorption. This scenario is usually reserved for treatment of peritonitis or with limited vascular access for drug administration. Correction of fluid overload is accomplished with high osmolar dialysis fluids. Higher dextrose concentrations (maximum 4.25%) can correct fluid overload rapidly at the risk of causing hyperglycemia. Fluid removal may also be increased with more frequent exchanges of the dialysate, but rapid osmotic transfer of water may result in hypernatremia. Because fluid removal is dependent on many factors (osmolar load of dialysate, individual peritoneal membrane transport characteristics, peritoneal membrane perfusion, etc), it is not possible to exactly control the hourly rate of fluid removal during peritoneal dialysis.

Even in small infants, hemodialysis can rapidly correct major metabolic and electrolyte disturbances as well as volume overload. The process is highly efficient. Systemic anticoagulation, usually with heparin, is typically required. Careful monitoring of the appropriate biochemical parameters is important. Note that during or immediately following the procedure, blood sampling will produce misleading results because equilibration between extravascular compartments and the blood will not yet have been achieved. Appropriate vascular access must be maintained. Hemodialysis is generally intermittent, daily to three times per week. If need be, CRRT may be used to maintain more minute-to-minute, continuous metabolic and fluid control especially in the hemodynamically unstable or septic patient. The choice of anticoagulation is typically based upon institutional preference and the clinical situation. Appropriately trained staff are needed to administer any dialytic therapy to children.

**Course & Prognosis**

The course and prognosis of acute kidney injury vary with the etiology. If severe oliguria occurs in acute tubular necrosis, it usually lasts about 10 days. Anuria or oliguria lasting longer than 4 weeks is concerning for progression to cortical necrosis and associated limited renal recovery. The diuretic phase of recovery from acute kidney injury begins with an increase in urinary output to large volumes of isosthenuric urine containing sodium levels of 80–150 mEq/L. The associated polyuria may persist for several days or weeks, and the care provider must ensure appropriate hydration to prevent prerenal azotemia or acute tubular necrosis. Urinary abnormalities usually disappear completely within a few months. If renal recovery does not ensue within about 4 weeks of oligoanuria, arrangements should be made for chronic dialysis and possible eventual renal transplantation. Some children requiring prolonged (>1 month) dialysis support will demonstrate recovery to varying degrees of chronic renal insufficiency but are obviously at high risk for eventual progression to ESRD. Children who have experienced significant acute kidney injury may require long-term follow-up with a nephrologist.
to glomerular disease or renal injury will characteristically require dialysis. A salt-wasting state can also occur. In generous volumes of poor quality urine even though they insufficiency. Some such children can continue to produce than fluid overload until very late in the course of renal lesions associated with impaired urinary concentration, polyuria and dehydration are more likely to be problems for gradual loss of functioning nephrons in progressive chronic renal failure, but complications of renal insufficiency appear when this compensatory ability is overwhelmed. In children who have structural kidney lesions associated with impaired urinary concentration, polyuria and dehydration are more likely to be problems than fluid overload until very late in the course of renal insufficiency. Some such children can continue to produce generous volumes of poor quality urine even though they require dialysis. A salt-wasting state can also occur. In contrast, children who develop chronic renal failure due to glomerular disease or renal injury will characteristically retain sodium and water with associated hypertension and eventual loss of urine output.

Metabolic acidosis and growth retardation occur early in chronic renal failure. Disturbances in calcium, phosphorus, and vitamin D metabolism leading to renal osteodystrophy and rickets require prompt attention. Increases in parathyroid hormone occur in response to decreased serum calcium from lack of renally activated vitamin D and/or rising serum phosphorus. The increase in parathyroid hormone, which improves renal tubular excretion of phosphorous, can maintain normal serum calcium and phosphate levels early in the course, but at the expense of the skeleton. Anemia due to decreased erythropoietin production can occur relatively early on as well.

Symptoms such as anorexia, nausea, and malaise occur late in chronic renal failure (generally < 30% renal function). These symptoms can be minimized if chronic renal failure has been detected early and associated complications treated, but refractory symptoms remain indications for renal replacement therapy. CNS abnormalities such as confusion and lethargy are very late symptoms, followed even later by stupor and coma. Such findings are unusual as children usually seek medical attention before deteriorating to this point, and the rise in BUN is typically gradual. Other late complications of untreated renal failure are platelet dysfunction and bleeding tendencies, pericarditis, and chronic fluid overload leading to congestive heart failure, pulmonary edema, and worsening hypertension.

Complications of chronic renal failure
- Anemia of chronic renal failure.
- Hyperphosphatemia/secondary hyperparathyroidism.
- Metabolic acidosis.
- Growth failure.
- Hypertension.
- Uremia.

Management of Complications

Treatment of chronic renal failure is primarily aimed at controlling the associated complications. Acidosis may be treated with sodium citrate or bicarbonate solutions, as long as the added sodium does not aggravate hypertension. Sodium restriction is advisable when hypertension is present. Hyperphosphatemia is controlled by dietary restriction and dietary phosphate binders (eg, calcium carbonate, sevelamer). Supplementation with vitamin D (cholecalciferol or ergocalciferol) and calcitriol is typically required. These measures target the prevention of renal osteodystrophy or rickets. Dietary potassium restriction will be necessary as the GFR falls. Diet must be maintained to provide the child’s daily requirements for optimal growth. Routine input from a renal dietitian is helpful in this regard.

Renal function must be monitored regularly (creatinine and BUN), and serum electrolytes, calcium, phosphorus, intact PTH, 25-OH-vitamin D, iron and ferritin, and hemoglobin and hematocrit levels monitored to guide changes in fluid and dietary management as well as dosages of phosphate binder, citrate buffer, vitamin D supplements, blood pressure medications, iron supplements, and epoetin alfa. Linear growth failure may be treated with daily subcutaneous human recombinant growth hormone; an adult height in the low-normal range is targeted. Care must be taken to avoid medications that
aggravate hypertension; increase the body burden of sodium, potassium, or phosphate; or increase production of BUN. Successful management relies greatly on education of the patient and family. Attention must also be directed toward the psychosocial needs of the patient and family as they adjust to chronic illness and the eventual need for dialysis and kidney transplantation. The multidisciplinary nephrology team works with each child/family to determine appropriate timing for chronic dialysis and/or kidney transplantation.

**Dialysis and Transplantation**

Chronic peritoneal dialysis (home-based) and hemodialysis provide lifesaving treatment for children prior to kidney transplantation. The best measure of the success of chronic dialysis in children is the level of physical and psychosocial rehabilitation achieved, such as continued participation in day-to-day activities and school attendance.

At present, the graft survival rate for living-related kidney transplants is 90% at 1 year, 85% at 2 years, and 75% at 5 years. With cadaveric transplantation, graft survivals are 76%, 71%, and 62%, respectively. Overall, the mortality rate is 4% for recipients of living-related donors and 6.8% for recipients of cadaver organs. These percentages are affected by the increased mortality, reported to be as high as 75%, in infants younger than age 1 year, primarily due to technical issues and complications of immunosuppression. A body weight of at least 10 kg is associated with a significantly improved survival rate. Adequate growth and well-being are directly related to acceptance of the graft, the degree of normal function, and the side effects of medications.

- **Clinical Findings**

A child is normotensive if the average recorded systolic and diastolic blood pressures are lower than the 90th percentile for age, sex, and height. The 90th percentile in the newborn period is approximately 85–90/55–65 mm Hg for both sexes. In the first year of life, the acceptable levels are 90–100/60–67 mm Hg. Incremental increases with growth occur, gradually approaching young adult ranges of 100–120/65–80 mm Hg in the late teens. A blood pressure between 90–95th percentile or exceeding 120/80 in adolescents is consistent with elevated blood pressure. Careful measurement of blood pressure requires correct cuff size and reliable equipment. The cuff should be wide enough to cover two-thirds of the upper arm and should encircle the arm completely without an overlap in the inflatable bladder. Ideally the child should be sitting quietly for 5 minutes before blood pressure is measured in the right arm, upon which norms are based. Although an anxious child may have an elevation in blood pressure, abnormal readings must not be too hastily attributed to this cause. Repeat measurement is helpful, especially after the child has been consoled. Manual blood pressure measurement should be pursued when automated readings are concerning; an exception is the neonatal period when manual assessment is technically difficult and appropriate size equipment often lacking. In cases where more detailed assessment is needed, 24-hour ambulatory blood pressure monitoring can be very valuable.

The causes of renal hypertension in the newborn period include (1) congenital anomalies of the kidneys or renal vasculature, (2) obstruction of the urinary tract, (3) thrombosis of renal vasculature or kidneys, and (4) volume overload. Some instances of apparent paradoxical elevations of blood pressure have been reported in clinical situations in which chronic diuretic therapy is used, such as bronchopulmonary dysplasia. Chronic hypoxia may have a role in vascular alterations, similar to what is seen with hypertension in older children with obstructive sleep apnea. Umbilical artery catheterization continues to be an important contributor to hypertension in infants and young children.

Infants and children with hypertension require careful evaluation to exclude a secondary cause of hypertension. These can include renal parenchymal or renovascular disease (renal arterial or venous thrombosis, congenital vascular stenosis), other vascular diseases (vasculitis, aortic coarctation), endocrine disorders (thyroid disease, cortisol excess, pheochromocytoma, congenital adrenal hyperplasia), monogenic hypertension (glucocorticoid remediable aldosteronism, Liddle syndrome, etc), and primary hyperaldosteronism. The family history of hypertension and cardiovascular disease should be reviewed with particular attention to early-onset hypertension. Primary hypertension is becoming increasingly common with a Western diet and limited routine exercise.
Routine laboratory studies include serum BUN, creatinine, and electrolytes and urinalysis. Abnormal BUN and creatinine would support underlying renal disease as the cause, and serum electrolytes demonstrating hypokalemic alkalosis suggest excess mineralocorticoid effect. Depending on the age of the child, routine assessment of serum lipids, glucose, A1C, hemoglobin, and thyroid function tests is indicated. Screening of plasma/urine catecholamines and metanephrines and/or serum cortisol should be obtained as clinically indicated. Pheochromocytoma is unusual in the setting of increasing obesity. Echocardiogram has been recommended for routine assessment of hypertension in children, but this practice has not been widely adopted. Careful assessment of distal pulses is necessary to exclude aortic coarctation clinically, and echocardiogram may be of value in select patients to exclude left ventricular hypertrophy. Renal ultrasonography with Doppler flow is helpful in determining the possible presence of renal scarring, urinary tract obstruction or renovascular flow disturbances as a cause of hypertension. However, the sensitivity and specificity of Doppler ultrasound for renal artery stenosis vary widely between institutions. Renal MRA or CTA is indicated when there is high suspicion for renal artery stenosis. A renal biopsy (which rarely reveals the cause of hypertension unless clinical evidence of renal disease is present) should be undertaken with special care in the hypertensive patient and preferably after pressures have been controlled by therapy. Figure 24–3 presents a suggested approach to the outpatient workup of hypertension.

**Initial Data**

**History:** symptoms of hypertension, UTI, renal/urologic disease, rash, joint pain/swelling, excessive sweating, constipation, diarrhea, dry skin, palpitations  
**Family history:** primary or early-onset hypertension, renal or cardiovascular disease, hyperlipidemia, diabetes mellitus, obesity  
**PE:** include lower extremity pulses and skin exam  
**Lab:** urinalysis, BUN, serum creatinine, electrolytes; consider plasma renin activity, TFTs, cortisol, plasma/urine metanephrines/ catecholamines, serum aldosterone  
**Imaging:** renal ultrasound with Doppler; echo if concern for aortic coarctation or LVH

**Figure 24–3.** Approach to the outpatient workup of hypertension. BP, blood pressure; BUN, blood urea nitrogen; CTA, computed tomography angiography; LVH, left ventricular hypertrophy; MRA, magnetic resonance angiography; TFT, thyroid function test; UTI, urinary tract infection.
Treatment

Acute Hypertensive Emergencies

A hypertensive emergency exists when CNS signs of hypertension appear, such as papilledema or encephalopathy. Retinal hemorrhages or exudates also indicate a need for prompt and effective control. Such children require appropriate management in the intensive care setting with consideration of continuous arterial BP monitoring and intravenous antihypertensive therapy. Whatever method is used to control emergent hypertension, medications for sustained control should also be initiated so that normal blood pressure will be maintained when the emergent measures are discontinued. The primary classes of useful antihypertensive drugs are (1) ACE inhibitors and angiotensin receptor blockers (the latter used less frequently in children based on less clinical experience and limitations in accurate dosing for smaller children), (2) calcium channel blockers, (3) α- and β-adrenergic blockers, (4) diuretics, and (5) vasodilators. Acute elevations of blood pressure not exceeding the 99th percentile in the asymptomatic patient may be treated with oral antihypertensives, aiming for progressive improvement and control within 48 hours.

Sublingual nifedipine is a rapid-acting calcium channel blocker that can be administered to acutely decrease severe hypertension. However, its use has fallen out of favor for acute management of hypertension in adults in whom an abrupt decline in blood pressure can significantly diminish perfusion of the coronary and cerebral arteries in the setting of underlying atherosclerosis. Alternatively, nicardipine is a very effective and generally well-tolerated antihypertensive that is administered via continuous intravenous infusion for control of systemic hypertension in children. Sodium nitroprusside is a very effective infusion to gain control of malignant hypertension, but long-term usage is limited by concern for rare thiocyanate toxicity, of particular concern when renal failure is present. Hydralazine is a vasodilator that can be administered intermittently by the intravenous route. Any vasodilator can induce reflex tachycardia and sodium retention, so concomitant administration of a β-blocker or diuretic may be indicated. Intravenous forms of β-blockers such as esmolol or labetalol are useful when there are no cardiac or respiratory contraindications to their use. Diuretics such as furosemide can be useful in the acute setting when there is evidence of intravascular volume overload.

Sustained Hypertension

Several choices are available for treatment (Table 24–3). A single drug such as an ACE inhibitor or a β-blocker (unless contraindicated, eg, with underlying asthma) may be adequate to treat mild hypertension. ACE inhibitors are often the preferred choice of pediatric nephrologists given the frequent renal etiology of hypertension. Diuretics are useful to treat renal insufficiency that is often associated with sodium and fluid retention, but the disadvantages of possible electrolyte Table 24-3. Antihypertensive drugs for ambulatory treatment in children ages 1–17 years.

imbalance must be considered. Calcium channel blockers are increasingly useful and appear well tolerated in children. Direct vasodilators such as hydralazine and minoxidil often require diuretics and/or β-blockers to combat associated sodium and fluid retention and reflex tachycardia. Although minoxidil is extremely effective in control of hypertension of a variety of etiologies, hirsutism is a significant side effect. The advice of a pediatric nephrologist should be sought in the management of acute and chronic hypertension in children.

There are many developmental, hereditary, or metabolic defects of the kidneys and collecting system. The clinical consequences include metabolic abnormalities, failure to thrive, nephrolithiasis, renal glomerular or tubular dysfunction, and chronic renal failure. Table 24–4 lists some of the major entities.

DISORDERS OF THE RENAL TUBULES

Three subtypes of RTA are recognized: (1) the classic form, called type I or distal RTA; (2) the bicarbonate-wasting form, called type II or proximal RTA; and (3) type IV, or hyperkalemic RTA, which is associated with hyporeninemic hypoaldosteronism or inherited in an autosomal manner. Types I and II and their variants are encountered most frequently in children. Type III is described historically as a combination of types I and II. Other primary tubular disorders in childhood, such as glycinuria, hyperuricosuria, or renal glycosuria, may result from a defect in a single tubular transport pathway (see Table 24–4).

Distal Renal Tubular Acidosis (Type I)

The most common form of distal RTA in childhood is the hereditary form. The clinical presentation is one of failure to thrive, anorexia, vomiting, and dehydration. Hyperchloremic metabolic acidosis, hypokalemia, and a urinary pH exceeding 6.5 are found. Concomitant hypercalcuria may lead to nephrocalcinosis, nephrolithiasis, and renal failure. Other situations that may be responsible for distal RTA are found in some of the entities listed in Table 24–4.

Distal RTA results from a defect in the distal nephron in the tubular transport of hydrogen ion or in the maintenance of a steep enough gradient for proper excretion of hydrogen ion. Historically the diagnosis could be established with an acid loading test, but this is rarely pursued currently. Instead, the findings of RTA with persistent elevation in urine pH despite acidosis, hypercalcuria or nephrocalcinosis, and relatively low requirement of alkali to normalize serum pH and bicarbonate concentration (1–3 mEq/kg/day) support a distal defect. Some forms of genetic distal RTA are associated with hearing loss. Correction of acidosis with citrate or less commonly bicarbonate reduces complications and improves growth. Distal RTA is often permanent. However, if renal damage from calcinosis is prevented, the prognosis with treatment is good.

Proximal Renal Tubular Acidosis (Type II)

Proximal RTA, the most common form of RTA in childhood, is characterized by failure to reabsorb bicarbonate appropriately in the proximal tubule with associated reduced serum bicarbonate concentration and normal anion gap hyperchloremic metabolic acidosis. Once a steady state is reached, the intact distal nephron appropriately excretes hydrogen ion, leading to a low urine pH.

Proximal RTA is often an isolated defect, and in the newborn can be considered an aspect of renal immaturity which improves with increasing gestational age. Proximal RTA in infants is accompanied by failure to thrive and sometimes hypokalemia. Secondary forms result from reflux or obstructive uropathy or occur in association with other tubular disorders (see Table 24–4). Due to bicarbonate wasting, children with proximal RTA typically require 5–20 mEq/kg/day citrate/bicarbonate to achieve normal serum pH and bicarbonate concentration.

Evaluation & Treatment

The diagnosis of RTA is made with the finding of normal anion gap, hyperchloremic metabolic acidosis in the absence of diarrhea, or intravascular volume depletion. A concomitant urine pH is helpful in many cases, as it is elevated in distal RTA despite the metabolic acidosis. The finding of hypophosphatemia or glycosuria should lead to further investigation of proximal tubular function (eg, Fanconi syndrome). A renal ultrasound should be obtained to exclude urinary tract obstruction (which can be seen with either proximal or distal RTA) and nephrocalcinosis (seen in distal RTA). A urine calcium to creatinine ratio may be helpful in the latter condition. In either proximal or distal RTA, citrate or bicarbonate supplementation is provided to target a serum bicarbonate level of 20–24 mEq/L, as an index of normal serum pH. Citrate solutions are more effective and often better tolerated than sodium bicarbonate. Sodium citrate contains 1 mEq/mL of Na+ and citrate. Potassium citrate contains 2 mEq/mL of citrate and 1 mEq/mL each of Na+ and K+. The medication is administered three times per day, targeting a trough serum bicarbonate at goal. Potassium supplementation may be required (and can often be accomplished simply with a change from sodium citrate to potassium citrate) because the added sodium load presented to the distal tubule may exaggerate potassium losses.

The prognosis is excellent in cases of isolated proximal RTA, especially when the problem is related to renal immaturity. Alkali therapy can usually be discontinued after several months to a few years. Growth should be normal, and the gradual increase in the serum bicarbonate level to greater than 24 mEq/L heralds the normalization of the threshold for proximal tubular bicarbonate reabsorption. If the defect is part of Fanconi syndrome or distal RTA, the prognosis depends on the underlying disorder or syndrome.

CYSTINOSIS

Cystinosis is the most common cause of Fanconi syndrome in children and results from mutations in the CTNS gene, which encodes the cystine transporter. There are three types of cystinosis: adult, adolescent, and infantile. The adult form is characterized by ocular cystinosis without renal involvement. In the adolescent and infantile types, cystine accumulation in lysosomes causes cell death in numerous organs, including the kidneys. Treatment with oral cysteamine aids in the metabolic conversion of cystine (unable to exit cells) to cysteine (able to exit cells) and delays intracellular
accumulation and associated complications, which include Fanconi syndrome with salt-wasting and functional nephrogenic diabetes insipidus, proximal RTA, hypophosphatemic rickets, eventual progression to ESRD, hypothyroidism, ocular cystinosis with eventual blindness, and neurologic deterioration. The infantile type is most common and the most severe. Characteristically, children present in the first or early second year of life with Fanconi syndrome and failure to thrive. If left untreated, ESRD is reached by 7–10 years of age in the infantile form. Whenever the diagnosis of cystinosis is suspected, slit-lamp examination of the corneas should be performed. Cystine crystal deposition causes an almost pathognomonic ground-glass “dazzle” appearance. Increased white blood cell cystine levels are diagnostic. The condition does not recur in transplanted kidneys, but ongoing cysteamine therapy is required to prevent complications in other organs.

Liddle syndrome is associated with constitutive activation of the epithelial sodium channel with amiloride or triamterene. Spironolactone is ineffective in this condition as due to the sodium and fluid retention. Treatment in Liddle syndrome is with a low-sodium diet and blockade of the sodium channel with amiloride or triamterene. Spironolactone is ineffective in this condition as aldosterone is typically suppressed.

**NEPHROGENIC DIABETES INSIPIDUS (NDI)**

Hereditary nephrogenic (vasopressin-resistant) diabetes insipidus is most often caused by X-linked mutations in the AVPR2 gene that encodes the vasopressin V₂ receptor. Autosomal (recessive and dominant) forms of NDI occur less commonly due to mutations of the AQP2 gene that codes for the collecting tubule water channel protein, aquaporin-2. Affected children often have a profound impairment in maximal urinary concentrating capacity, which rarely exceeds 100 mOsm/kg H₂O. Genetic counseling and mutation testing are available.

Acquired nephrogenic diabetes insipidus (NDI) is observed in numerous conditions including sickle cell anemia, chronic pyelonephritis, hypokalemia, hypercalcemia, Fanconi syndrome, obstructive uropathy, chronic renal insufficiency, and lithium treatment.

The symptoms of NDI include polyuria and polydipsia. In severe cases, water intake is preferred to formula, leading to failure to thrive. In some children, particularly if the solute intake is unrestricted, adjustment to an elevated serum osmolality may develop. Children with genetic NDI are particularly susceptible to episodes of dehydration, fever, vomiting, and hypernatremia when access to free water is limited.

**HYPOKALEMIC ALKALOSIS (BARTTER SYNDROME, GITEMAN SYNDROME, & LIDDLE SYNDROME)**

There are a number of genetic tubular disorders which result in hypokalemic metabolic alkalosis. Bartter syndrome is characterized by severe hypokalemic, hypochloremic metabolic alkalosis, extremely high levels of circulating renin and aldosterone, and a paradoxical absence of hypertension. On renal biopsy (rarely pursued in the current era), a striking juxtaglomerular hyperplasia is seen. A neonatal form of Bartter syndrome is thought to result from mutations in two genes (NKCC2, ROMK) affecting nephron Na⁺-K⁺ or K⁺ transport. These patients typically have a history of polyhydranmios and following birth have recurrent life-threatening episodes of fever and dehydration with the aforementioned electrolyte and acid-base disturbances, hypercalcemia, and early-onset nephrocalcinosis. Classic Bartter syndrome presenting in infancy with polyuria and growth retardation (but not nephrocalcinosis) is thought to result from mutations in a chloride channel gene. Gitelman syndrome occurs in older children and features episodes of muscle weakness and tetany associated with severe hypokalemia, and hypomagnesemia. These children have hypocalciuria. Treatment with prostaglandin inhibitors and potassium-conserving diuretics (eg, amiloride) and potassium and magnesium supplements where indicated is beneficial in Bartter or Gitelman syndrome. These are lifelong conditions which require ongoing electrolyte supplementation.

Oculo-cerebro-renal syndrome (LOWE SYNDROME)

Lowe syndrome results from various mutations in the OCRL1 gene, which codes for a Golgi apparatus phosphatase. Affected males have anomalies involving the eyes, brain, and kidneys. The physical stigmata and degree of mental retardation vary with the location of the mutation. In addition to congenital cataracts and buphthalmos, the typical facies includes prominent epicanthal folds, frontal prominence, and a tendency to scaphocephaly. Muscle hypotonia is a prominent finding. The renal abnormalities are tubular and include hypophosphatemic rickets with low serum phosphorus levels, low to normal serum calcium levels, elevated serum alkaline phosphatase levels, proximal RTA, and aminoaciduria. Renal treatment includes alkali therapy, phosphate replacement, and vitamin D support. Progressive glomerulosclerosis likely results from progressive renal tubular injury and may lead to chronic renal failure and end-stage renal disease between the second and fourth decades of life.

The diagnosis can be suspected on the basis of a history of polydipsia and polyuria. The family history may be informative in hereditary cases while a review of the patient’s medical history, medications, and serum chemistries can help identify a source of acquired NDI. The diagnosis is confirmed by performing a water deprivation test, during which time serum and urine osmolality are assessed and either arginine vasopressin or desmopressin administered to assess tubular response. When hereditary NDI is suspected, it is imperative that a water deprivation test be performed in the hospital in a controlled setting. Due to the severe concentrating defect, restricting water intake overnight at home in such children can lead to severe intravascular volume depletion and hyperosmolality. In addition to hyperglycemia, the differential diagnosis of polydipsia and polyuria includes primary polydipsia, which occurs in children as young as infancy.

In infants with NDI, it is usually best to allow water as demanded and to restrict salt intake. Caregivers must be aware of the risks of dehydration and hypernatremia if fluid intake is restricted either due to lack of provision by the caregiver or inability to keep fluids down (eg, vomiting). A low-salt diet limits the amount of urine that must be produced for daily solute excretion. Due to the need for high-volume free water intake, caloric intake may be limited and affected children often benefit from routine follow-up with a renal dietitian. Treatment with hydrochlorothiazide decreases urine volume by limiting the amount of free water delivered to the distal nephron for excretion. Prostaglandin inhibitors such as indomethacin are efficacious by decreasing renal blood flow, thereby diminishing GFR, and by preventing reclamation of the AQP2 water channel from the apical membrane of the collecting duct cell. Prostaglandin inhibitors, however, are associated with risk of gastritis/ulceration.

Cystinuria

Cystinuria is primarily an abnormality of amino acid transport across both the enteric and proximal renal tubular epithelium. There are at least three biochemical types. In the first type, the bowel transport of basic amino acids and cystine is impaired, but transport of cysteine is not impaired. In the renal tubule, basic amino acids are again rejected by the tubule, but cystine absorption appears to be normal. The reason for cystinuria remains obscure. Heterozygous individuals have no aminoaciduria. The second type is similar to the first except that heterozygous individuals excrete excess cystine and lysine in the urine, and cystine transport in the bowel is normal. In the third type, only the nephron is involved. The only clinical manifestations are related to stone formation: ureteral colic, dysuria, hematuria, proteinuria, and secondary UTI. Urinary excretion of cystine, lysine, arginine, and ornithine is increased.

The most reliable way to prevent stone formation is to maintain a constantly high free-water clearance. This involves generous fluid intake. Alkalization of the urine is helpful. If these measures do not prevent significant renal lithiasis, the use of tiopronin is recommended.

Primary Hyperoxaluria

Oxalate in humans is derived from the oxidative deamination of glycine to glyoxylate, the serine-glycolate pathway, and from ascorbic acid. At least two enzymatic blocks have been described. Type I is a deficiency of liver-specific peroxisomal alanine-glyoxylate aminotransferase. Type II is glyoxylate reductase deficiency. Recently a type III primary hyperoxaluria has been described in association with increased mitochondrial 4-hydroxy-2-oxoglutarate aldolase activity; this type appears to be milder than types I or II.

Excess oxalate combines with calcium to form insoluble deposits in the kidneys, lungs, and other tissues, beginning during childhood. The joints are occasionally involved, but the main effect is on the kidneys, where progressive oxalate deposition leads to fibrosis and eventual renal failure.
URINARY TRACT INFECTIONS

It is estimated that 8% of girls and 2% of boys will acquire UTIs in childhood. Girls older than age 6 months have UTIs far more commonly than boys, whereas uncircumcised boys younger than 3 months have more UTIs than girls. Circumcision reduces the risk of UTI in boys. The density of distal urethral and periurethral bacterial colonization with uropathogenic bacteria correlates with the risk of UTI in children. Most UTIs are ascending infections. Specific adhesins present on the fimbria of uropathogenic bacteria allow colonization of the uroepithelium in the urethra and bladder and increase the likelihood of UTI. The organisms most commonly responsible for UTI are fecal flora, most frequently *E. coli* (> 85%), *Klebsiella*, *Proteus*, other gram-negative bacteria, and, less frequently, *Enterococcus* or coagulase-negative staphylococci.

**Pathogenesis**

Dysfunctional voiding, which is uncoordinated relaxation of the urethral sphincter during voiding, leads to incomplete emptying of the bladder, increasing the risk of bacterial colonization. Similarly, any condition that interferes with complete emptying of the bladder, such as constipation, VUR, urinary tract obstruction, or neurogenic bladder, increases the risk of UTI. Poor perineal hygiene, structural abnormalities of the urinary tract, catheterization, instrumentation of the urinary tract, and sexual activity increase the risk as well.

The inflammatory response to pyelonephritis may produce renal parenchymal scars. Such scars in infancy and childhood may contribute to hypertension, renal disease, and renal failure later in life.

**Clinical Findings**

**Symptoms and Signs**

Newborns and infants with UTI have nonspecific signs, including fever, hypothermia, jaundice, poor feeding, irritability, vomiting, failure to thrive, and sepsis. Strong, foul-smelling or cloudy urine may be noted. Preschool children may have abdominal or flank pain, vomiting, fever, urinary frequency, dysuria, urgency, or enuresis. School-aged children commonly have classic signs of cystitis (frequency, dysuria, and urgency) or pyelonephritis (fever, vomiting, and flank pain). Costovertebral tenderness is unusual in young children, but may be demonstrated by school-aged children. Physical examination should include attention to blood pressure determination, abdominal examination, and a genitourinary examination. Urethritis, poor perineal hygiene, herpes simplex virus infection, or other genitourinary infections may be apparent on examination.

**Laboratory Findings**

Screening urinalysis indicates pyuria (> 5 WBCs/hpf) in most children with UTI, but some children can have sterile pyuria without UTI. White cells from the urethra or vagina may be present in urine or white cells may be in the urine because of a renal inflammatory process. The leukocyte esterase test correlates well with pyuria, but has a similar false-positive rate. The detection of urinary nitrite by dipstick is highly correlated with enteric organisms being cultured from urine. Most young children (70%) with UTI have negative nitrite tests, however. They empty their bladders frequently, and it requires several hours for bacteria to convert ingested nitrates to nitrite in the bladder.

The gold standard for diagnosis remains the culture of a properly collected urine specimen. Collection of urine for urinalysis and culture is difficult in children due to frequent contamination of the sample. In toilet-trained, cooperative, older children, a midstream, clean-catch method is usually satisfactory. Although cleaning of the perineum does not improve specimen quality, straddling of the toilet to separate the labia in girls, retraction of the foreskin in boys, and collecting midstream urine significantly reduce contamination. In infants and younger children, bladder catheterization or suprapubic collection is necessary in most cases to avoid contaminated samples. Bagged urine specimens are helpful if negative. Specimens that are not immediately cultured should be refrigerated and kept cold during transport. Any growth is considered significant from a suprapubic collection. Bagged urine specimens are helpful if negative. Specimens that are not immediately cultured should be refrigerated and kept cold during transport. Any growth is considered significant from a suprapubic culture. Quantitative recovery of 10⁵ cfu/mL or greater is considered significant from clean-catch specimens, and 10⁴–10⁵ is considered significant from catheterized specimens. Usually the recovery of multiple organisms indicates contamination.

Asymptomatic bacteriuria is detected in 0.5%–1.0% of children who are screened with urine culture. Asymptomatic bacteriuria, as seen commonly in children requiring chronic bladder catheterization, is believed to represent colonization of the urinary tract with nonuropathogenic bacteria. Treatment in such cases may increase the risk of symptomatic...
UTI by eliminating nonpathogenic colonization. Screening urine cultures in asymptomatic children are, therefore, generally discouraged.

Imaging

Because congenital urologic abnormalities increase the risk of UTI, a renal ultrasound, which is a noninvasive study, is recommended for children with UTI. The finding of significant hydroureter or other concerning urinary tract abnormalities on screening ultrasound warrants further imaging. A voiding cystourethrogram is no longer routinely recommended following first UTI in childhood, although the sensitivity of the renal ultrasound for detection of significant VUR varies widely in medical literature. VUR, a congenital abnormality present in about 1% of the population beyond infancy, is graded using the international scale (I—reflux into ureter; II—reflux to the kidneys; III—reflux to kidneys with dilation of ureter only; IV—reflux with dilation of ureter and mild blunting of renal calyces; V—reflux with dilation of ureter and blunting of renal calyces). Reflux is detected in 30–50% of children presenting with a UTI at 1 year of age and younger. The natural history of reflux is to improve, and 80% of reflux of grades I, II, or III will resolve or significantly improve within 3 years following detection. Significant debate exists in the literature regarding appropriate radiographic imaging for UTI and best management of VUR, including indications for and value of surgical intervention and/or prophylactic antibiotics.

Treatment

Antibiotic Therapy

Management of UTI is influenced by clinical assessment. Very young children (age < 3 months) and children with dehydration, toxicity, or sepsis continue to be admitted to the hospital and treated with parenteral antimicrobials. Older infants and children who are not seriously ill can be treated as outpatients. Initial antimicrobial therapy is based on prior history of infection and antimicrobial use, as well as presumed location of the infection in the urinary tract.

Most uncomplicated cystitis can be treated with amoxicillin, trimethoprim–sulfamethoxazole, or a first-generation cephalosporin. These antimicrobials are concentrated in the lower urinary tract, and high cure rates are common. There is significant variation in rates of antimicrobial resistance, so knowledge of the rates in the local community is important. More seriously ill children are initially treated parenterally with a third-generation cephalosporin or less commonly aminoglycoside. The initial antimicrobial choice is adjusted after culture and susceptibility results are known. The recommended duration of antimicrobial therapy for uncomplicated cystitis is 7–10 days. For sexually mature teenagers with cystitis, fluoroquinolones such as ciprofloxacin and levofloxacin for 3 days are effective and cost-effective. Short-course therapy of cystitis is not recommended in children, because differentiating upper and lower tract disease may be difficult and higher failure rates are reported in most studies of short-course therapy.

Acute pyelonephritis is usually treated for 10 days. In nontoxic children older than 3 months of age who are not vomiting, oral treatment with an appropriate agent can be used. In sicker children, parenteral therapy may be required initially. Most of these children can complete therapy orally once symptomatic improvement has occurred. A repeat urine culture 24–48 hours after beginning therapy is not needed if the child is improving and doing well.

Prophylactic Antimicrobials

Selected children with frequently recurring UTI may benefit from prophylactic antimicrobials. In children with high-grade VUR, prophylactic antimicrobials may be beneficial in reducing UTI, as an alternative to surgical correction, or in the interval prior to surgical therapy. Some experts recommend surgical correction of higher-grade reflux, particularly grade V. Trimethoprim—sulfamethoxazole and nitrofurantoin are approved for prophylaxis. The use of broad-spectrum antimicrobials leads to colonization and infection with resistant strains.

Children with dysfunctional voiding may benefit from prophylactic antimicrobials; however, addressing the underlying dysfunctional voiding is most important.

QA/QI in Pediatric Nephrology

The North American Pediatric Renal Trials & Collaborative Study (NAPRTCS) (www.naprtcs.org) has collected clinical information on children undergoing kidney transplant since 1987, and, as of 2013, included information on 11,603 kidney transplants in 10,632 patients. Since the first data analysis in 1989, NAPRTCS reports have documented marked improvements in outcome after kidney transplant in addition to identifying factors associated with both favorable and poor outcomes. Acute rejection rates continue to decline with improvements in short- and long-term graft survival. Recently, NAPRTCS data have been used as a
source of benchmark for pediatric kidney transplant centers, providing center-specific outcomes for chronic kidney disease, dialysis, and transplant patients for comparison with national statistics.

The Standardized Care to Improve Outcomes in Pediatric ESRD (SCOPE) Collaborative helps pediatric dialysis centers minimize dialysis-related infections in peritoneal dialysis and hemodialysis patients through encouragement of multicenter adherence to recommended best practices. As of 2013, the Collaborative demonstrated a 27% reduction in peritonitis rates, and new efforts are being targeted at the hemodialysis population.

Since 1997, the National Kidney Foundation (NKF) (https://www.kidney.org) has published clinical practice guidelines in nephrology known as KDOQI—Kidney Disease Outcomes Quality Initiative. There are numerous guidelines addressing the best practice care of patients with chronic kidney disease. Although primarily directed toward adult patients, the number of guidelines that address pediatric care is increasing.

Neurologic Assessment & Neurodiagnostics

HISTORY & EXAMINATION

History

Even in this era of increasingly sophisticated neurodiagnostic testing, the assessment and diagnosis of a child with a possible neurologic disorder still hinges on a detailed history and examination. The standard pediatric history and physical examination are presented in Chapter 9. In particular, determining the temporal progression of the neurologic signs and symptoms (acute vs chronic, progressive vs static, episodic vs continuous) can direct the evaluation. Episodic events, such as headaches or seizures, warrant emphasis on the symptoms preceding, during, and succeeding the event. Spells can also be videotaped, allowing the examiner to obtain first-hand observation of important details that can clarify the diagnosis. Both acute and chronic neurologic symptoms may be associated with other organ system involvement, such as joint pain, changes in appetite or bowel/bladder habits, or a preceding viral illness, which can provide additional clues to the diagnosis. Birth history should include assessment of fetal movement and whether the infant was breech or vertex. A thorough past medical history and family history can illuminate risk factors for certain neurologic disorders. Social history should include school performance, preferred activities, and travel history.

Neurologic Examination

A general physical examination is essential in any neurologic assessment. Growth parameters and head circumference should be charted (see Chapter 3). A developmental assessment, often with an appropriate screening tool, is fundamental for every neurologic evaluation of an infant or young child (see Chapter 3 for details of developmental landmarks and example screening tools). The specifics of the neurologic examination are determined by the age of the child and the ability to cooperate with the examination. Expected infant reflexes and other age-related examination findings are included in Chapter 2. The hallmark of neurologic diagnosis is localization—determining where within the nervous system the “lesion” is located. While not all childhood neurologic disorders are easily localized, the part of the nervous system involved—for example, central versus neuromuscular—can often guide further evaluation and diagnosis.

Table 25–1 outlines components of the neurologic examination—mental status, cranial nerves, motor (including tone, muscle bulk, and strength), reflexes, sensation, coordination, and gait. Much of the examination of the frightened or active child is, by necessity, observational, and the examiner must capitalize on moments of opportunity while maintaining a systematic approach to avoid overlooking a key component. Playing games engages a toddler or preschooler; activities such as throwing a ball, stacking blocks, hopping, jogging, counting, and drawing (circles, lines) can reduce anxiety and allow assessment of fine and gross motor coordination, balance, and handedness. In the older child, “casual” conversation can reveal both language and cognitive competence.

DIAGNOSTIC TESTING

Electroencephalography

Electroencephalography (EEG) is a noninvasive method for recording neuronal electrical activity in the brain. The background patterns of the EEG vary by both age (infant, toddler, or adolescent) and clinical state (awake, drowsy, or asleep). Intermittent activity, such as slowing of the background, often reflects disordered central nervous system (CNS) function. The EEG has its greatest clinical applicability in the

</table>

The EEG is rarely diagnostic in isolation, but is rather only one part of the child’s clinical picture. Routine EEG, obtained in the outpatient setting, is usually brief (<30 minutes). Therefore, events of interest are usually not recorded. If the child is unable to cooperate, it may be impossible to obtain a study, or the study may be uninterruptable due to artifact from movement, crying, etc. Medications used for sedation of an uncooperative child, especially barbiturates and benzodiazepines, may produce artifact or iatrogenic changes in the EEG, which can confuse interpretation and may decrease the likelihood of recording abnormalities such as epileptiform discharges. In addition, children without a history of epilepsy may, in fact, have an abnormal EEG. EEG findings such as those occasionally seen in migraine, learning disabilities, or behavior disorders are often nonspecific and do not reflect structural brain damage or dysfunction. When questions arise regarding the clinical
significance of EEG findings, consultation with a pediatric neurologist is appropriate.

Due to more prolonged duration, ambulatory EEG obtained over 24–72 hours can be useful in capturing and assessing events to ascertain if they are due to epileptic seizures. Likewise, recording the EEG during nocturnal polysomnograms can help differentiate between nonepileptic sleep-related events from nocturnal epileptic seizures.

Prolonged or continuous inpatient EEG recordings are useful in the assessment of patients with altered mental status, suspected nonconvulsive status epilepticus, and drug-induced coma, as well as infants with hypoxic ischemic encephalopathy. The EEG is less commonly helpful in determining electrocerebral silence (brain death).

A continuous video-EEG recording, obtained in conjunction with inpatient admission to an epilepsy monitoring unit (EMU), allows assessment of the patient with medically intractable epilepsy. The children are admitted to a specialized inpatient unit for up to a week or more, sometimes with reduction or discontinuation of medication, increasing the likelihood of recording an event. Localization of the seizure focus by EEG recording during seizures can indicate candidacy of surgical resection or other surgical procedures for patients who have failed medical therapy. Correlating video with EEG has also proven useful in characterizing spells that may or may not be seizures.

**Evoked Potentials**

Visual-, auditory-, or somatosensory-evoked potentials (evoked responses) can be obtained by repetitive stimulation of the retina by light flashes, the cochlea by sounds, or a nerve by galvanic stimuli. These stimuli result in cortical responses recorded from the scalp surface. The presence or absence of evoked potential waves and their latencies from the time of the stimuli can be useful in some specific situations, such as the use of visual-evoked potentials (VEP) in patients with optic neuritis, multiple sclerosis (MS), or other demyelinating diseases, as well as somatosensory-evoked potentials (SSEP) in the monitoring of patients during spinal surgery for rapid identification of potentially reversible spinal cord injury. Similar techniques are used in other surgeries when there is risk of nerve injury such as craniofacial surgeries. However, evoked potentials are not routinely obtained for evaluation of neurologic disorders. One important exception is the use of brainstem auditory-evoked responses (BAER), which are now considered standard for screening hearing in neonates.

**Lumbar Puncture**

Spinal fluid is usually obtained by inserting a small-gauge needle (eg, No. 22) through the L3–L4 intervertebral space into the thecal sac while the patient is lying in a lateral recumbent position. Radiographic guidance and sedation may be necessary in some patients. After an opening pressure is measured, fluid is removed to examine for evidence of infection, inflammation, or metabolic disorders (Table 25–2). Special staining techniques can be used for mycobacterial and fungal infections, and further testing can be performed for specific viral agents, antibody titer determinations, cytopathologic studies, lactate and pyruvate concentrations, amino acid levels, and neurotransmitter analysis.

Lumbar puncture is imperative when bacterial meningitis is suspected. Caution must be exercised, however, when signs of increased intracranial pressure (eg, papilledema) or focal neurologic signs are present that might indicate a substantial risk of precipitating tentorial or tonsillar herniation.

**Genetic/Metabolic Testing**

The diagnostic yield of genetic and metabolic evaluation of children with global developmental delay or intellectual disability (GDD/ID) depends on the specific testing done. Chromosomal microarray testing is diagnostic in almost 8% of children with GDD/ID and in other appropriate clinical situations; tests for metabolic disorders have a yield of up to 5%. Thus, focused assessments for genetic disorders should be part of the evaluation of the child with GDD/ID.

**Electromyography & Nerve Conduction Velocity Testing**

Electromyography (EMG) and nerve conduction velocity testing (NCV) are used for assessment of multiple neuromuscular disorders, including spinal muscular atrophy, Guillain-Barre syndrome, defects in neuromuscular transmission such as myasthenia gravis and infantile botulism, myopathies, acquired and hereditary neuropathies, leukodystrophies, and disorders associated with central as well as peripheral demyelination.

NCV is performed by introducing a small current into peripheral nerves and calculating the conduction velocity of the stimulus. EMG records spontaneous and volitional electrical activity of skeletal muscle tissue. It requires placement of needles into selected muscles. For more details, refer to section within this chapter entitled "Disorders of Childhood Affecting Muscles."

**PEDIATRIC NEURORADIOLOGIC PROCEDURES**

**Computed Tomography**

CT scanning allows visualization of intracranial contents by obtaining a series of cross-sectional roentgenograms. Current scanning techniques allow rapid acquisition of data, often without sedation. CT scanning has high sensitivity (88%–96% of lesions larger than 1–2 cm can be seen), but low specificity (tumor, infection, or infarct may look the same).

ADEM, acute disseminated encephalomyelitis; AIDS, acquired immunodeficiency syndrome; CMV, cytomegalovirus; CSF, cerebrospinal fluid; EBV, Epstein-Barr virus; HSV, herpes simplex virus; IL-8, interleukin 8; LDH, lactate dehydrogenase; MRI, magnetic resonance imaging; MS, multiple sclerosis; PCR, polymerase chain reaction; PMN, polymorphonuclear neutrophil; RBC, red blood cell; TNF, tumor necrosis factor; WBC, white blood cell.

\[ a \text{CSF-IgG index} = \frac{\text{CSF IgG/serum IgG}}{\text{CSF albumin/serum albumin}}. \]

\[ b \text{Many studies document pitfalls in using these ratios due to WBC lysis. Clinical judgment and repeat lumbar punctures may be necessary to rule out meningitis in this situation.} \]

\[ c \text{CSF WBC (predicted) = CSF RBC } \times (\text{blood WBC/blood RBC}) \times \text{O:P ratio} = \text{(observed CSF WBC)/(predicted CSF WBC). Also, do WBC:RBC ratio. If O:P ratio } \leq 0.01, \text{ and WBC:RBC ratio } \leq 1:100, \text{ meningitis is absent.} \]
It is particularly useful for assessment of head trauma, allowing excellent visualization of intracranial blood. It allows visualization of the ventricular system to assess hydrocephalus. It is useful in determining the presence of intracranial calcifications such as those associated with intrauterine infections, tubers in patients with tuberous sclerosis complex, etc. Intravenous injection of iodized contrast media may be helpful in some situations but is not routinely used for the purposes of neuroimaging. CT angiography (CTA) is possible using contrast and specialized techniques to visualize vascular anatomy and can replace catheter angiography in evaluation of stroke. When ordering CT scan of the head as well as repeated CT scans, consider radiation exposure. A single CT scan of the head is approximately 2 millisieverts (mSv; typical chest x-ray PA view = 0.02 mSv), which equates to ~8 months of exposure to the naturally occurring radiation in the environment. The additional lifetime risk of malignancy is thought to be 1 brain tumor per 10,000 patients in the 10 years following CT exposure.

**Magnetic Resonance Imaging**

MRI provides high-resolution images of soft tissues by detecting the response (resonance) of hydrogen protons to electromagnetic radiation. The strength of MRI signals varies with the relationship of water to protein and lipid in tissue. MRI can provide information about the histological, physiological, and biochemical status of tissues, as well as gross anatomic features. Sedation usually is necessary for MRI scans in children who are unable to lie still for 45 minutes to avoid movement artifact.

MRI is used to assess a wide variety of neurologic disorders such as tumors, edema, ischemic and hemorrhagic lesions, vascular disorders, inflammation, demyelination, CNS infection, metabolic disorders, and degenerative processes. Because bone does not produce artifact in the images, the posterior fossa contents can be studied far better with MRI than with CT scans, allowing imaging of the brainstem, blood vessels, and cranial nerves. The lack of ionizing radiation exposure is an advantage over CT.

Magnetic resonance angiography (MRA) or venography (MRV) is used to visualize large extra- and intracranial blood vessels, though they are not as sensitive as conventional angiography. Perfusion-weighted imaging and diffusion-weighted imaging (DWI) (measuring random motion of water molecules) are used to evaluate brain ischemic penumbra and cytotoxic edema in acute stroke as well as toxic and metabolic brain disorders.

MR spectroscopy (MRS) assesses biochemical changes in CNS tissue, measuring signals of increased cellular activity and oxidative metabolism such as occur, for example, in brain tumors.

Newer functional MRI (fMRI), can localize various brain functions such as language and motor activity by assessing blood oxygenation changes in an area of interest during language or motor tasks. The axonal tracts of neurologic pathways, such as the optic radiations or motor system, can be identified using diffusion tensor imaging (DTI). These techniques generally require a team involving a neuropsychologist and radiologist to derive specific paradigms for testing and evaluation of imaging, as well as a cooperative patient.

**Positron Emission Tomography**

Positron emission tomography (PET) uses radiolabeled substrates such as intravenously administered fluorodeoxyglucose to measure the metabolic rate at given sites within the brain, producing three-dimensional reconstructions for localization of CNS function. These scans may be co-registered with a traditional CT scan or MRI, allowing more precise localization of functional processes, particularly for example in preoperative evaluation for epilepsy surgery. PET is most often performed in the interictal state. The information from PET scans complement EEG, single-photon emission computerized tomography (SPECT), and MRI findings to aid in defining the epileptogenic zone ("focus") of a patient’s seizures. PET co-registered with CT scans or MRI scans is particularly useful for assessing systemic tumors, as well as general assessment of the CNS.

**Single-Photon Emission Computerized Tomography (SPECT Scans)**

SPECT scans image cerebral blood flow using a radioactive tracer (typically technetium-99m) to produce multiple cuts similar to those obtained in CT scans. This allows virtual three-dimensional visualization of vascular blood flow. It is useful in assessment of patients for epilepsy surgery, aiding in identification of increased blood flow in a seizure focus during a seizure. In children with brain tumors, SPECT can help differentiate tumor recurrence from post-treatment changes, assessing the response to treatment, directing biopsy, and planning therapy. Regional cerebral blood flow can be assessed in children with strokes due to vascular stenosis and moyamoya syndrome.

**Ultrasoundography**

Ultrasoundography (US) allows assessment of brain structures quickly with easily portable equipment, without ionizing radiation, and at about one-fourth the cost of CT scanning. Sedation is usually not necessary, and the procedure can be repeated as often as needed without risk to the patient. The thin skull and the open anterior fontanel in neonates facilitate imaging of the brain to screen and follow neonates at risk for intracranial hemorrhage and detect hydrocephalus, periventricular ischemic lesions, major brain and spine malformations, and calcifications. Once the fontanels start to close, this modality is no longer useful due to inability of ultrasound waves to penetrate bone.
**Cerebral Angiography**

Arteriography remains useful in the diagnosis of cerebrovascular disorders, particularly ischemic and hemorrhagic stroke, as well as potentially operable vascular malformations. In some brain tumors, arteriography may be used to define the nature of tumors and for surgical planning. Since cerebral angiography uses traditional x-ray to produce images, there is significant exposure to ionizing radiation.

**Myelography**

Radiographic examination of the spine may be indicated in some cases of spinal cord tumors, myelitis, or various forms of spinal dysraphism, and in the rare instance of herniated disks in children, although MRI has largely replaced sonography, CT, and myelography for such purposes.

**DISORDERS AFFECTING THE NERVOUS SYSTEM IN INFANTS & CHILDREN**

**ALTERED STATES OF CONSCIOUSNESS (COMA)**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Reduction or alteration in cognitive and affective mental functioning and in arousability or attentiveness.
- Acute onset.

Consciousness encompasses both the patient’s level of wakefulness and the patient’s ability to interact with the environment. The neurologic substrate for consciousness is the ascending reticular activating system (RAS) comprised of the reticular formation in the brainstem, thalamic intralaminar nuclei, and portions of the hypothalamus. Dysfunction of the cerebral cortex, especially bilateral lesions, can also cause coma.

**Clinical Findings**

**A. Symptoms and Signs**

Many terms, including obtundation, lethargy, somnolence, stupor, and coma, are used to describe the continuum from fully alert and aware, to complete unresponsiveness. Physicians can use a scale, such as the commonly used Glasgow Coma Scale summarized in Table 25–3, but they should also provide qualitative descriptions such as, “opens eyes with painful stimulus, but does not respond to voice.” These descriptions help subsequent observers quantify unconsciousness and evaluate changes in the patient’s condition. *Coma* is defined by the complete absence of wakefulness and interaction with the environment for at least 1 hour. When coma persists, evaluation for the presence of sleep-wake cycles or absence of all brain function can further delineate the severity of the disorder of consciousness (Table 25–3).

- Persistent or permanent vegetative state (PVS) denotes a chronic condition (persistent if > 4 weeks; permanent if > 3–12 months, depending on etiology) in which...
sleep-wake cycles are preserved, but the patient has no awareness of self or the environment. PVS is sometimes referred to as “wakefulness without awareness.”

- **Minimally conscious state** (MCS) denotes patients who demonstrate sleep-wake cycles and some residual degree of interaction with the environment. For instance, these patients occasionally may have purposeful movements. Thus, MCS involves “partial preservation of consciousness.”

- **Brain death** (death by neurologic criteria) refers to patients in coma who have cessation of all brain function, including cortical activity, brainstem reflexes, and spontaneous respirations.

### B. Laboratory and Imaging Diagnostics

Medical causes account for 90% of cases of coma in children; structural causes comprise the remaining 10% (Table 25–4). If the cause of the coma is not obvious, emergency laboratory tests must be obtained, such as blood glucose, complete blood count, urine studies (obtained by catheterization if necessary), pH and electrolytes (including bicarbonate), serum urea nitrogen, liver function tests, and ammonia. Urine, blood, and even gastric contents can be sent for toxin screens if the underlying cause is not obvious. Infection is a common cause (30%), and blood cultures and lumbar puncture are necessary. However, papilledema or focal neurologic deficits are relative contraindications to lumbar puncture prior to imaging. In obscure cases of coma, additional testing might include oxygen and carbon dioxide partial pressures, serum and urine osmolality, porphyrins, lead, amino acids, and urine organic acids.

If severe head trauma, intracranial hemorrhage, or increased intracranial pressure is suspected, an emergency CT scan or MRI is necessary. CT is typically faster and superior to MRI for detecting small hemorrhages, but MRI is more sensitive in detecting stroke and anoxic brain injury. Abbreviated MRI protocols are also increasingly being used to rule out hemorrhage and hydrocephalus, sparing the patient from unnecessary ionizing radiation exposure from a CT. Bone windows on CT or skull radiographs may demonstrate skull fractures better. The absence of skull fracture does not rule out coma caused by closed head trauma, such as from abusive head trauma. Treatment of head injury associated with coma is discussed in detail in Chapter 12.

EEG can sometimes aid in diagnosing the cause of coma, such as with nonconvulsive status epilepticus, a specific abnormality (such as periodic lateralized epileptiform discharges seen with herpes encephalitis), or focal slowing (such as with stroke or cerebritis). The EEG also may correlate with the stage of coma and add prognostic information.

### Differential Diagnosis

Conditions mistaken for coma:

- **Locked-in syndrome** describes patients who are conscious (awake and aware) but cannot demonstrate interactive-ness with their environment due to a massive loss of motor function, typically due to a lesion in the pons. Vertical eye movements may be preserved.

- **Akinetic-mutism** denotes a patient who is awake and aware, but does not speak, initiate movements, or follow commands, typically due to lesions of the frontal lobes.

- **Catatonia** refers to patients with abnormal alertness and awareness (though typically not completely absent) secondary to psychiatric illness. Patients often retain the ability to maintain trunk and limb postures.

### Treatment

As with any emergency, the clinician must first stabilize the comatose child using the ABCs of resuscitation. Signs of intracranial pressure and impending brain herniation are another priority of the initial assessment. Bradycardia, high blood pressure, and irregular breathing (Cushing’s Triad) or third nerve palsy (with the eye deviated down and out), and a “blown” pupil (unilateral pupillary dilation) indicate prompt neurosurgical consultation and head CT. Initial treatment of impending herniation includes elevating the head of the bed to 15–30 degrees and providing moderate hyperventilation. The use of mannitol, hypertonic saline, pharmacologic coma, hypothermia, and drainage of cerebrospinal fluid (CSF) are more heroic measures covered in detail in Chapter 14.

### Prognosis

About 50% of children with nontraumatic causes of coma have a good outcome. Outcome can be successfully predicted at an early stage in approximately two-thirds of patients by assessing coma severity, extraocular movements, pupillary reactions, motor patterns, blood pressure, temperature, and seizure type. In patients with severe head trauma, a Glasgow Coma Scale ≤ 5, hypothermia, hyperglycemia, and coagulation disorders are factors associated with an increased risk of mortality. Other characteristics such as the need for assisted respiration, the presence of increased intracranial pressure, and the duration of coma are not significantly predictive.

AGN, acute glomerulonephritis; SIADH, syndrome of inappropriate antidiuretic hormone secretion.
A seizure is a sudden, transient disturbance of brain function, manifested by involuntary motor, sensory, autonomic, or psychic phenomena, alone or in any combination, often accompanied by alteration or loss of consciousness. Seizures can be caused by any factor that disturbs brain function. They may occur after a metabolic, traumatic, anoxic, or infectious insult to the brain (classified as symptomatic seizures), or spontaneously without prior known CNS insult. Genetic mutations are increasingly identified in many patients without prior known cause of seizures.

Epilepsy is defined as two seizures that are separated by at least 24 hours, a single seizure associated with a greater than 60% risk of recurrence or the diagnosis of an epilepsy syndrome. During childhood, the incidence is highest in the newborn period. Prevalence flattens out after age 10–15 years. The chance of having a second seizure after an initial unprovoked episode in a child is about 50%. The risk of recurrence after a second unprovoked seizure is 85%. Sixty-five to seventy percent of children with epilepsy will achieve seizure remission with appropriate medication.

Classification

The International League Against Epilepsy (ILAE) has established classifications of seizures and epilepsy syndromes. Seizures are classified as either focal, previously called partial (with suspected seizure onset that can be localized to one part of the brain), generalized (likely involving the whole brain or a network of the brain), or “unknown” if it is not clear if they are focal or generalized.

There are several types of generalized seizures that are recognized with the new classification: generalized tonic-clonic, absence (typical, atypical, and with special features), myoclonic, myoclonic atonic, tonic, clonic, and atonic seizures.

New nomenclature is suggested for focal seizures that is based on the presentation of the seizure. The description of the seizure is most beneficial with suggested terms such as “without alteration of awareness,” “hyperkinetic,” “emotional,” or “autonomic” seizure. Such descriptions allow better classification of seizures.

Epilepsy syndromes are defined by the nature of the seizures typically present, age of onset, EEG findings, and other clinical factors. New terminology has been developed for epilepsy syndromes to reflect our growing understanding of underlying etiology. The newest classification allows for classification based on the information that is available at the time of the seizure, with a hierarchical approach whereby patients can be classified by types of seizures, epilepsy type (focal, generalized, combined or unknown), or a specific epilepsy syndrome. In parallel, patients may have an etiologic diagnosis (structural, genetic, infectious, etc.) and may have comorbid diagnoses (ADHD, depression, anxiety, etc.). Tools to aid in the classification of seizures and epilepsy syndromes can be found at the International League Against Epilepsy website https://www.ilae.org/education/diagnostic-manual.

1. Seizures & Epilepsy in Childhood

Characterizing the seizure and subsequent epilepsy syndrome is necessary for accurate diagnosis, which will determine the nature of further evaluation and treatment. This also assists with prognosis (Table 25–5) and research of specific syndromes.

Clinical Findings

A. Symptoms and Signs

Seizures are stereotyped paroxysmal clinical events; the key to diagnosis is usually in the history. Not all paroxysmal events are epileptic. A detailed description of seizure onset is important in determining if an event is a seizure and if there is localized onset (focal seizure). Events prior to, during, and after the seizure need to be ascertained. Although observers often initially recall little except generalized convulsive activity because of its dramatic appearance, careful detailed questions can lead to a better description of the event and situation in which it occurred. An aura may precede the clinically apparent seizure and indicates focal onset. The patient may describe a feeling of fear, numbness or tingling in the fingers, or bright lights in one visual field. The specific symptoms may help define the location of seizure onset (eg, déjà vu suggests temporal lobe onset). Often, the child does not recall or cannot define the aura, though the family may note alterations in behavior at the onset. Videotapes of events have been extremely useful.

Postictal states can be helpful in diagnosis. After many focal seizures and most generalized convulsive seizures,

<tbody>
<tr>
<td>Neonatal seizures</td>
<td>Birth–2 wk</td>
<td>Can be any seizure type, can be very subtle.</td>
<td>Neurologic insults (hypoxia/ischemia; intracranial hemorrhage) present more in first 3 days or after 8th day; metabolic disturbances alone between 3rd and 8th days; hypoglycemia, hypocalcemia, hyper- and hyponatremia. Drug withdrawal. Pyridoxine dependency. Other metabolic disorders. CNS infections. Structural abnormalities. Genetic causes increasing recognized.</td>
<td>May correlate poorly with clinical seizures. Focal spikes or slow rhythms; multifocal discharges. Electroclinical dissociation may occur: electrical seizure without clinical manifestations.</td>
<td>Lumbar puncture; CSF PCR for herpes, enterovirus; serum Ca(^{2+}), PO(_4)(^{3–}); serum and CSF glucose, Mg(^{2+}); BUN, amino acid screen, blood ammonia, organic acid screen, TORCHS, other metabolic testing if suspected. Ultrasound or CT/MRI for suspected intracranial hemorrhage and structural abnormalities.</td>
<td>Benzodiazepines, phenobarbital, IV or IM; if seizures not controlled, add phenytoin IV. Recent experience with levetiracetam and topiramate. Treat underlying disorder. Seizures due to brain damage often resistant to anticonvulsants. When cause in doubt, stop protein feedings until enzyme deficiencies of urea cycle or amino acid metabolism ruled out.</td>
<td></td>
</tr>
<tr>
<td>Epileptic spasms</td>
<td>3–18 mo, usually about 6 mo</td>
<td>Abrupt, usually but not always symmetrical adduction or flexion of limbs with flexion of head and trunk; or abduction and extensor movements (similar to Moro reflex). Occur in clusters typically upon awakening. Associated irritability and regression in development.</td>
<td>Etiology identified in approximately two-thirds fitting structural/metabolic or genetic. Tuberous sclerosis in 5%–10%. TORCHS, homeobox gene mutations, ARX, and other genetic mutations.</td>
<td>Hypsarrhythmia (chaotic high-voltage slow waves or random spikes [90%]); other abnormalities in 10%. Rarely normal at onset. EEG normalization early in course usually correlates with reduction of seizures; not helpful prognostically regarding mental development.</td>
<td>Funduscopic and skin examination, amino and organic acid screen. Chromosomes TORCHS screen, CT, or MRI scan. Trial of pyridoxine. Consider gene panels.</td>
<td>ACTH. Vigabatrin, especially if tuberous sclerosis. B(_6) (pyridoxine) trial. In resistant cases, topiramate, zonisamide, valproic acid, lamotrigine, ketogenic diet. Early treatment leads to improved outcome. Occasionally, surgical resection of cortical malformation.</td>
<td></td>
</tr>
<tr>
<td>Febrile convulsions</td>
<td>3 mo–6 y (maximum 6–18 mo); most common childhood seizure (incidence 2%)</td>
<td>Usually generalized seizures, &lt; 15 min; rarely focal in onset. May lead to status epilepticus. Recurrence risk of second febrile seizure 30% (50% if younger than 1 y of age); recurrence risk is same after status epilepticus.</td>
<td>Nonneurologic febrile illness (temperature rises to 39°C or higher). Risk factors: positive family history, day care, slow development, prolonged neonatal hospitalization.</td>
<td>Normal interictal EEG, especially when obtained 8–10 days after seizure. Therefore, not useful unless complicating features.</td>
<td>Lumbar puncture in infants or whenever suspicion of meningitis exists.</td>
<td>Treat underlying illness, fever. Diazepam orally, 0.3–0.5 mg/kg, divided 3 times daily during illness may be considered. Diastat rectally for prolonged (&gt; 5 min) seizure. Prophylaxis with phenobarbital or valproic acid rarely needed.</td>

postictal sleep typically occurs. However, postictal changes
are not seen after generalized absence seizures. It also helps
to determine if there were loss of speech after the seizure
(suggesting left hemisphere involvement) or if the patient
were able to respond and speak in short order. The parent
may report lateralized motor activity (eg, the child’s eyes
may deviate to one side or the child may experience dys-
tonic posturing of a limb). Motor activity without impaired
awareness supports the diagnosis of focal seizures as do
impaired awareness and automatisms previously defined as
a “complex partial seizure.”

In contrast, generalized seizures usually manifest with acute
loss of consciousness, usually with generalized motor activity.
Tonic posturing, tonic-clonic activity, or myoclonus (spasms)
may occur. In children with generalized absence seizures,
behavioral arrest may be associated with automatisms such as
blinking, chewing, or hand movements, making it difficult to
differentiate between absence seizures and focal seizures.

Frequently, the child presenting with a presumed first
seizure has experienced unrecognized seizures before the
event that brings the child to medical attention. Focal,
myoclonic, and absence seizures, in particular, may not be
recognized except in retrospect. Thus, careful questioning
regarding prior events is important in the child being evalu-
ated for new onset of seizures. Events that are perceived as
seizures but are not epileptic, such as syncope events, can
also be determined by careful questioning.

B. Diagnostic Evaluation

Many factors determine the extent and urgency of the diag-
nostic evaluation, such as the child’s age, the severity and
type of seizure, whether the child is ill or injured, and the
clinician’s suspicion about the underlying cause. Seizures in
early infancy often have an underlying cause that is struc-
tural, genetic, or metabolic and will guide prognosis and
management. Therefore, the younger the child, the more
extensive must be the diagnostic assessment.

It is generally accepted that every child with new onset of
unprovoked seizures should be evaluated with an EEG and
MRI, although this need not be done emergently. An EEG
is very unlikely to yield clinically useful information in the
child with a febrile seizure. Other diagnostic studies should
be used selectively.

Metabolic abnormalities are seldom found in the well
child with seizures. Unless there is a high clinical suspicion
of serious medical conditions (eg, uremia, hyponatremia,
hypocalcemia, etc), “routine” laboratory tests rarely yield
clinically significant information. Special studies may be nec-
essary in circumstances that suggest an acute systemic etiol-
ogy for a seizure, for example, in the presence of apparent
renal failure, sepsis, or substance abuse. Emergent imaging
of the brain is usually not necessary in the absence evidence
of trauma or of acute abnormalities on examination.

C. Electroencephalography

The limitations of EEG even with epilepsy, for which it
is most useful, are considerable. A routine EEG captures
electrical activity during a very short period, usually
20–30 minutes. Thus, it is useful primarily for defining
interictal activity (except for the fortuitous recording of a
clinical seizure or in situations when seizures are easily
provoked such as childhood absence epilepsy). A seizure
is a clinical phenomenon; an EEG showing epileptiform
activity may confirm and clarify the clinical diagnosis (for
instance, defining an epilepsy syndrome), but it is only
occasionally diagnostic (see EEG under diagnostic section
earlier in chapter).

Differential Diagnosis

It is extremely important to be accurate in the diagnosis of
epilepsy and not to make the diagnosis without ample proof.
To the layperson, epilepsy often has connotations of brain
damage and limitation of activity. A person so diagnosed
may be excluded from certain occupations in later life. It
is often very difficult to change an inaccurate diagnosis of
many years’ standing.

Misinterpretation of behaviors in children is the most
common reason for misdiagnosis. Psychogenic nonepileptic
events are much less common in children than in adults
but must be considered even in the young or cognitively
impaired child. The most commonly misinterpreted behav-
iors are inattention in school-aged children with attention
disorders, stereotypies in children with autistic spectrum
disorder, sleep-related movements, habit movements such
as head-banging and so-called infantile masturbation (some-
times referred to as gratification movements), and gastro-
esophageal reflux in very young (often impaired) infants.
Some of the common nonepileptic events that mimic seizure
disorder are listed in Table 25–6.

Complications & Sequelae

A. Psychosocial Impact

Emotional disturbances, especially depression but also anxi-
ety, anger, and feelings of guilt and inadequacy, often occur
in the patient as well as the parents of a child with epilepsy.
Actual or perceived stigmas as well as issues regarding “dis-
closure” are common. There is an increased risk of suicide
in people with epilepsy. Schools often limit activities of chil-
dren with epilepsy inappropriately and stigmatize children
by these limitations.

Epilepsy with onset in childhood has an impact on adult
function. Adults with early onset of epilepsy, even when well
controlled, are less likely to complete high school, have less
adequate employment, and are less likely to marry. Persis-
tent epilepsy results in significant dependence; even when

<tr>
<td><strong>Breath-holding attacks (cyanotic and pallid)</strong> (see below) Cyanotic: Age 6 mo–3 y. Always precipitated by trauma and fright. Cyanosis; sometimes stiffening, tonic (or jerking-clonic) convolution (anoxic seizure). Patient may sleep following attack. Family history positive in 30%. Electroencephalogram (EEG) is not useful. No medication treatment is useful but if the patient is found to be iron-deficient supplementation may reduce events. However, in general reassurance is most important. Pallid: Usually, there is no apparent precipitant although fright may precipitate. Pallor may be followed by seizure (anoxic-ischemic). Vagally mediated (heart-slowing), like adult syncope. EEG is not useful.</td>
<td><strong>Benign nocturnal myoclonus</strong> Common in infants and may last even up to school age. Focal or generalized jerks (the latter also called hypnic or sleep jerks) may persist from onset of sleep on and off all night. A video record for physician review can aid in diagnosis. EEG taken during jerks is normal, proving that these jerks are not epilepsy. Treatment is reassurance.</td>

</tr>
<tr>
<td><strong>Shuddering</strong> Shuddering or shivering attacks can occur in infancy and may be a forerunner of essential tremor in later life. Often, family history is positive for tremor. Shivering may be very frequent. EEG is normal. There is no clouding or loss of consciousness. <strong>Gastroesophageal reflux (Sandifer syndrome)</strong> Seen more commonly in children with cerebral palsy or brain damage; reflux of acid gastric contents may cause pain that cannot be described by child. Unusual posturing (dystonic or other) of head and neck or trunk may occur, an apparent attempt to stretch the esophagus or close the opening. There is no loss of consciousness, but eye rolling, apnea, and occasional vomiting may simulate a seizure. An upper gastrointestinal series, cine of swallowing, sometimes even an EEG (normal during episode) may be necessary to distinguish from seizures. <strong>Parasomnias (night terrors, sleep talking, walking, “sit-ups”)</strong> Ages 3–10 y. Usually occur in first sleep cycle (30–90 min after going to sleep), with crying, screaming, and autonomic discharge (pupils dilated, perspiring, etc). May last only a few minutes or be more prolonged. Child goes back to sleep and has no recall of event next day. Sleep studies (polysomnogram and EEG) are normal. Sleep talking and walking and short “sit-ups” in bed are fragmentary arousals. If a spell is recorded, EEG shows arousal from deep sleep, but behavior seems wakeful. Child needs to be protected from injury and gradually settled down and taken back to bed. Medications may be considered in rare instances. <strong>Infantile masturbation/gratification movements</strong> Rarely in infants, repetitive rocking or rubbing motions may simulate seizures. Infant may look out of contact, be poorly responsive to environment, and have autonomic expressions (eg, perspiration, dilated pupils) that may be confused with seizures. Observation by a skilled individual, sometimes even in a hospital setting, may be necessary to distinguish from seizures. EEG is normal between and during attacks. Interpretation and reassurance are the only necessary treatment. <strong>Conversion reaction/psychogenic nonepileptic seizures</strong> Up to 50% of patients with nonepileptic seizures also have epilepsy. Episodes may involve writhing, pelvic thrusting, tonic movements, bizarre jerking and thrashing, or even apparently sudden unresponsiveness. Children may be developmentally delayed. Spells must often be seen or recorded with a video recorder to distinguish from epilepsy but are sometimes so bizarre they are easily differentiated. A normal EEG during a spell is a key diagnostic feature. Combattiveness is common; self-injury and incontinence, rare. Within the pediatric population, most patients with psychogenic nonepileptic seizures have a good prognosis without deep seated psychological trauma. <strong>Migraine</strong> On occasion, migraine can be associated with an acute confusional state. Usual migraine prodrome of spots before the eyes, dizziness, visual field defects, followed by headache and then agitation confusion is present. History of other, more typical migraine with severe headache and vomiting but without confusion may aid in diagnosis. Severe headache with vomiting as child comes out of spell may aid in distinguishing the attack from epilepsy. However, partial seizures, while brief, may be associated with more prolonged postictal agitation and confusion. Other seizure manifestations are practically never seen (eg, tonic-clonic movements, falling, complete loss of consciousness). EEG in migraine is usually normal and seldom has epileptiform abnormalities often seen in patients with epilepsy. Migraine and epilepsy are sometimes linked: Benign occipital epilepsy may present with migraine-like visual aura and headache. There may be migraine-caused cortical ischemia which leads to later epilepsy. Postictal headache can be confused with migraine. <strong>Temper tantrums and rage attacks</strong> Child often reports amnesia for events during spell. Attacks are usually precipitated by frustration or anger, often directed either verbally or physically, and subside with behavior modification and isolation. EEGs are generally normal but seldom obtained during an attack. It should be noted that directed violence is very uncommon following partial seizures but severe agitation can occur. <strong>Staring spells</strong> Teachers often make referral for absence or “petit mal” seizures in children who stare or seem preoccupied at school. Helpful in the history is the lack of these spells at home (eg, before breakfast, a common time for absence seizures). Lack of other epilepsy in child or family history often is helpful. These children often have difficulties with school and cognitive or learning disabilities. Child can generally be brought out of spell by a firm command or touch and if event is interruptible they are unlikely to be seizures. EEG is sometimes necessary to confirm that absence seizures are not occurring. <strong>Benign nocturnal myoclonus</strong> Common in infants and may last even up to school age. Focal or generalized jerks (the latter also called hypnic or sleep jerks) may persist from onset of sleep on and off all night. A video record for physician review can aid in diagnosis. EEG taken during jerks is normal, proving that these jerks are not epilepsy. Treatment is reassurance. <strong>Gastroesophageal reflux (Sandifer syndrome)</strong> Seen more commonly in children with cerebral palsy or brain damage; reflux of acid gastric contents may cause pain that cannot be described by child. </table>
epilepsy is successfully treated, patients with long-standing epilepsy often do not become independent due to driving restrictions and safety concerns.

B. Cognitive Delay

Children living with epilepsy, particularly with untreated or poorly controlled seizures, can develop reduced cognition and memory. Clearly, epileptic encephalopathy (ie, epileptic activity or frequent seizures are contributing to worse neurocognitive function) does occur, particularly in young children with epilepsies such as infantile spasms (West syndrome), Dravet syndrome, and Lennox-Gastaut syndrome. The impact of persistent partial seizures on development is less clear, although persistent temporal lobe seizures in adults are associated with cognitive dysfunction. It is not likely that interictal epileptiform activity contributes to cognitive impairment in older children, although increased epileptiform burden has been demonstrated to cause mild cognitive problems in some disorders previously thought to be benign, such as benign epilepsy with central temporal spikes (BECTS). Continuous epileptiform activity in sleep is associated with Landau-Kleffner syndrome (acquired epileptic aphasia) and the syndrome of electroencephalographic status epilepticus in sleep (ESES), both of which are associated with cognitive decline.

“Pseudodementia” may occur in children with poorly controlled epilepsy because their seizures interfere with their learning. Depression is a common cause of impaired cognitive function in children with epilepsy. Anticonvulsants are less likely to cause such interference at usual therapeutic doses, although phenobarbital, topiramate, and zonisamide may produce cognitive impairment, which is reversible on discontinuing the medication. Psychosis also can occur after seizures or as a side effect of medications.

C. Injury and Death

Children with epilepsy are at far greater risk of injuries than the general pediatric population. Physical injuries, especially lacerations of the forehead and chin, are frequent in atonic (previously called static) seizures (so-called drop attacks), necessitating protective headgear. In all other seizure disorders in childhood, injuries as a direct result of a seizure are not as common, although drowning, injuries related to working in kitchens, and falls from heights remain potential risks for all children with active epilepsy. It is therefore extremely important to stress “seizure precautions,” in particular water safety. Showers are recommended over bathing as they decrease the likelihood of drowning. Ultimately, patients with epilepsy should not participate in activities that could result in serious injury in the case of sudden loss of consciousness, without taking precautions to address that possibility.

However, for most activities simple accommodations allow individuals with epilepsy to lead very normal lives.

The greatest fear of a parent of a child with new-onset of epilepsy is the possibility of death or brain injury. There is an increased risk of premature death in children with epilepsy, especially those who have not achieved seizure control. Most of the mortality in children with epilepsy is related to the underlying neurologic disorder, not the seizures. Sudden unexpected death with epilepsy (SUDEP) is a rare event in children. Although children with epilepsy have an increased risk of death, SUDEP occurs in only 1–2:10,000 patient-years. The greatest risk for SUDEP is in children with medically uncontrolled epilepsy. The etiology of SUDEP is not yet known and there is no current proven strategy to prevent SUDEP other than seizure control. Identifying life-threatening disorders (eg, identifying patients with cardiac arrhythmias, especially prolonged QT syndrome) as the cause of misdiagnosed epilepsy is clearly of utmost importance. While SUDEP is rare, increased mortality in children with epilepsy should be mentioned when counseling families.

Treatment

The ideal treatment of acute seizures is the correction of specific causes. However, even when a biochemical disorder, a tumor, meningitis, or another specific cause is being treated, anti-seizure drugs are often still required.

A. First Aid

Caregivers should be instructed to protect the patient against self-injury. Turning the child to the side is useful for preventing aspiration. Placing any objects in the mouth of a convulsing patient or trying to restrain tonic-clonic movements may cause worse injuries than a bitten tongue or bruised limb and could potentially become a choking hazard. Parents are often concerned that cyanosis will occur during generalized convulsive seizures, but it is rare for clinically significant hypoxia to occur. Mouth-to-mouth resuscitation is rarely necessary and is unlikely to be effective.

For prolonged seizures (those lasting over 5 minutes), acute home treatment with benzodiazepines such as rectal diazepam gel (Diastat) or intranasal midazolam may be administered to prevent the development of status epilepticus and has proven to be safe even when administered by nonmedical professionals, including teachers and day care providers, when appropriately instructed.

B. Antiepileptic Drug (AED) Therapy

1. Drug selection—Several issues should be considered when choosing an anti-seizure medication including effectiveness, side effects (good or bad), risk, and what other
medications the patient is already taking. Some medications are good for focal seizures but can make generalized seizures worse (e.g., oxcarbazepine and carbamazepine), while other medications are good for most seizure types and are relatively safe (levetiracetam). Many medications may be effective for most seizure types but are thought to be particularly good for certain seizures (clobazam for myoclonic seizures). It is worth noting that most of this “knowledge” is based on experience and expert opinion rather than comparative effectiveness or randomized control trials. In some cases, side effects can help guide treatment; for example, topiramate tends to suppress appetite whereas valproic acid often precipitates weight gain. When weighing risks, side effects, and potential effectiveness, one must consider the impact on the patient and their family’s life.

2. **Treatment strategy**—The goal of anti-seizure treatment is “no seizures and no side effects.” The child with a single seizure has a 50% chance of seizure recurrence. Thus, it is usually not necessary to initiate therapy until the diagnosis of epilepsy is established, that is, there is a second seizure. The seizure type and epilepsy syndrome as well as potential side effects will determine which drug to initiate as discussed earlier. If monotherapy fails, a second, and when necessary a third medication may be required to help reduce seizure frequency. Care must be taken when using multiple anti-seizure medications, as this increases the chance of side effects and often does not substantially improve seizure control. Therefore, if anti-seizure medications with different mechanisms of action may improve their combined tolerability and effectiveness.

3. **Long-term management and discontinuation of treatment**—Therapy should be continued until the patient is free of seizures for at least 1–2 years. In about 75% of patients, seizures will not recur following discontinuation of medication after 2 years of remission. Variables such as younger age at onset, normal EEG, undetermined etiology, and ease of controlling seizures carry a favorable prognosis, whereas identified etiology, later onset, continued epileptiform EEG, difficulty in establishing initial control of the seizures, polytherapy, generalized tonic-clonic or myoclonic seizures, as well as an abnormal neurologic examination are associated with a higher risk of recurrence. Most AEDs (with the exception of barbiturates and benzodiazepines) can be withdrawn over 6–8 weeks. Recurrent seizures affect up to 25% of children who attempt withdrawal from medications. Recurrence of seizures is most likely within 6–12 months of discontinuing medications. Therefore, seizure safety precautions will need to be reinstated, including driving restriction. If seizures recur during or after withdrawal, AED therapy should be reinstated and maintained for at least another 1–2 years. The majority of children will again achieve remission of their seizures.

**C. Alternative Treatments**

1. **Adrenocorticotropic hormone (ACTH) and corticosteroids**—Treatment with ACTH or oral corticosteroids is the standard of care for infantile spasms. Duration of therapy is guided by cessation of clinical seizures and normalization of the EEG. Vigabatrin is an alternative treatment that is also considered standard of care for infantile spasms and has been shown to be superior for infantile spasms resulting from tuberous sclerosis. All other treatments for infantile spasms have a lower likelihood of being effective.

   **Precautions:** It is important to guard against infections, provide GI prophylaxis, and follow for possible hypertension, and discuss the cushingoid appearance and its disappearance. Oral corticosteroids should not be withdrawn suddenly. Side effects in some series occur in up to 40% of patients. In some regions of the country, prophylaxis against *Pneumocystis* infection may be required. Careful and frequent follow-up is necessary. Visiting nurse services and partnering with a medical home can be very helpful in surveillance such as monitoring blood pressure, weight, and potential adverse effects.

2. **Ketogenic diet**—Fasting has been described to stop seizures for centuries and a diet high in fat and low in protein and carbohydrates will result in ketosis and simulate a fasting state. Such a diet has been observed to decrease and even control seizures in some children. This diet should be monitored very carefully (by a clinical team familiar with the ketogenic diet) to ensure sufficient nutrients, including vitamins and minerals, to maintain overall health. Recent reports suggest potential efficacy with a modified Atkins diet or a low-glycemic index diet in older and higher functioning children who will not accept the ketogenic diet.

   The mechanism for the anticonvulsant action of the ketogenic diet is not understood. The ketogenic diet requires close adherence and full cooperation of all family members. However, when seizure control is achieved by this method, acceptance of the diet is usually excellent. Families must be cautioned that abrupt withdrawal (accidental or purposeful) of the diet can precipitate seizures and even status epilepticus. Increased use of the ketogenic diet and family support groups have increased the number of palatable recipes for patients and families on the ketogenic diet.

   As with all therapies, potential adverse effects can occur with the ketogenic diet. These include acidosis and hypoglycemia, particularly on initiation of the diet. The child should be admitted to a center well versed in managing ketogenic diet to start this treatment. Close follow-up will help prevent risk for renal stones, pancreatitis, and acidosis. In addition, vitamin and minerals need to be followed carefully to avoid deficiences, especially carnitine, iron, and vitamin D.

3. **Vagus nerve stimulator (VNS)**—The VNS is a pacemaker-like device that is implanted below the clavicle and
attached to the left vagus nerve. A cycle of electrical stimulation of the nerve is established, which has an antiepileptic effect, reducing seizures by at least 50% in over half the children treated. In addition, an emergency mode that is activated by swiping a magnet (of abrupt tachycardia on newer models) may interrupt a seizure. With current technology, the battery in the stimulator may last 7 or more years in many patients.

D. Surgery

An evaluation for epilepsy surgery is indicated for all children with medically intractable partial epilepsy (generally defined as failure of two anti-seizure medications at effective doses). The evaluation and surgery should be performed at a center with expertise in epilepsy surgery and which has a dedicated neurosurgeon, epileptologists and neuropsychologists with experience in epilepsy surgery.

The first surgery for treatment of epilepsy took place over 100 years ago, and surgery is now established as an appropriate treatment option for adults and children with epilepsy refractory to medical treatment. Evaluation for possible surgical treatment should begin as soon as it is apparent that a child with focal onset seizures is not responding to standard therapy. Medication resistant (“refractory”) epilepsy is usually defined as failure of two or three anti-epileptic drugs alone or as combination therapy to control seizures. Advances in technology allow for definition and removal of the epileptogenic focus even in young infants. Many centers now have access to variety of resources for identifying the region of seizure onset. Ultimately, the chance of seizure freedom can range from 50% to 95% depending on the clinical circumstance. Some children with more generalized seizures may qualify for other types of surgery, such as corpus callosotomy, that aim to reduce seizure burden.

E. General Management of the Child with Epilepsy

1. Education—The initial diagnosis of epilepsy is often devastating for families. The patient and parents must be helped to understand the nature of epilepsy and its management, including etiology, prognosis, safety issues, and treatment options.

Excellent educational materials are available for families of a child with epilepsy, both in print and online. An excellent website is http://www.epilepsy.com. Materials on epilepsy—including pamphlets, monographs, films, and videotapes suitable for children and teenagers, parents, teachers, and medical professionals—may be purchased through the Epilepsy Foundation: 8301 Professional Place, Landover, MD 20785; (800) 332–1000. The foundation’s local chapter and other community organizations are able to provide guidance and other services. Support groups exist in many regions for older children and adolescents and for their parents and others concerned.

2. Privileges and precautions in daily life—"No seizures and no side effects" is a motto established by the Epilepsy Foundation. The child should be encouraged to live as normal a life as possible. Children should engage in physical activities appropriate to their age and social group. After seizure control is established, swimming is generally permissible with a buddy system or adequate lifeguard coverage. Scuba diving and high climbing without safety harness is generally not allowed. There are no absolute contraindications to any other sports, although some physicians recommend against contact sports. Physical training and sports are usually to be welcomed rather than restricted. There is some literature that suggests that exercise decreases overall seizure burden and may also be helpful to maintain good bone health.

Depression, anxiety, and attentional difficulties are common comorbidities of epilepsy, particularly in adolescents, and need to be treated as they can be as (or more) debilitating as the seizures. Sleep deprivation and alcohol should be avoided as they can be triggers for seizures in patients with epilepsy. Prompt attention should be given to intercurrent illnesses that can also trigger seizures.

Although every effort should be made to control seizures, treatment must not interfere with a child’s ability to function normally. A child may do better having an occasional mild seizure than being so heavily sedated that function at home, in school, or at play is impaired. Therapy and medication adjustment often require much art and fortitude on the physician’s part.

3. Driving—Driving becomes important to most young people at age 15 or 16 years. Restrictions for persons with epilepsy and other disturbances of consciousness vary from state to state. In most states, a learner’s permit or driver’s license will be issued to an individual with epilepsy if he or she has been under a physician’s care and free of seizures for at least 6–12 months provided that the treatment or basic neurologic problems do not interfere with the ability to drive. A guide to this and other legal matters pertaining to persons with epilepsy is published by the Epilepsy Foundation, and its legal department may be able to provide additional information.

4. Pregnancy—Contraception (especially interaction of oral contraceptive with some AEDs), childbearing, potential teratogenicity of AEDs, and the management of pregnancy should be discussed as soon as appropriate with the adolescent young woman with epilepsy. Daily use of vitamin preparations and high-dose folic acid can be protective against neural tube defects. For the pregnant teenager with epilepsy, management by an obstetrician conversant with the use of AEDs in pregnancy is appropriate. The patient should be cautioned against discontinuing her medications during pregnancy. The possibility of teratogenic effects of AEDs, such as facial clefts (two to three times increased risk),
must be weighed against the risks from seizures. All AEDs appear to have some risk for teratogenicity, although valproate carries a particularly high risk for spinal dysraphism as well as being associated with cognitive issues in children exposed to valproate in utero. Dosing may need to be adjusted frequently during pregnancy as blood volume expands. Frequent AED blood levels may be helpful in making these adjustments.

5. School intervention and seizure response plans—
Schools are required by federal law to work with parents to establish a seizure action plan for their child with epilepsy. A template for such a plan is available on the Epilepsy Foundation website at http://epilepsy.prod.acquia-sites.com/sites/core/files/atoms/files/seizure-action-plan-pdf_0.pdf. These plans usually require the approval of the child’s physician. Schools are sometimes hesitant to administer rescue medications. Often, information from the physician, especially that obtained from the Epilepsy Foundation website, will relieve anxieties. School authorities should be encouraged to avoid needless restrictions and to address the emotional and educational needs of all children with disabilities, including epilepsy. The local affiliates of the Epilepsy Foundation can often provide support and education for both families and schools.

2. Status Epilepticus
Status epilepticus is usually defined as a clinical or electrical seizure lasting at least 15 minutes, or a series of seizures without complete recovery over a 30-minute period. Importantly, this time cut-off keeps getting shorter as more evidence accrues that even relatively short seizures may be harmful to the brain. After 30 minutes of seizure activity, hypoxia and acidosis occur, with depletion of energy stores, cerebral edema, and structural damage. Eventually, high fever, hypotension, respiratory depression, and even death may occur. Status epilepticus is a medical emergency. Aggressive treatment of prolonged seizures may prevent development of status epilepticus. It is generally recommended that treatment with benzodiazepines at home for prolonged seizures be initiated 5 minutes after onset of a seizure. There are currently several forms of benzodiazepines that can be administered safely at home, including rectal suppository. There are currently several forms of benzodiazepines that can be administered safely at home, including rectal suppository. Fosphenytoin may be given more rapidly in the same dosage as phenytoin (1000 mg maximum); monitor with blood pressure and ECG. Fosphenytoin may be given more rapidly in the same dosage as phenytoin (1000 mg maximum); monitor with blood pressure and ECG. Fosphenytoin may be given more rapidly in the same dosage as phenytoin (1000 mg maximum); monitor with blood pressure and ECG.

Status epilepticus is classified as (1) convulsive (the common generalized tonic-clonic type) or (2) nonconvulsive (characterized by altered mental status or behavior with subtle or absent motor components). Absence status, or spike-wave stupor, and focal status epilepticus are examples of the nonconvulsive type. An EEG may be necessary to aid in diagnosing nonconvulsive status because patients sometimes appear merely stuporous and lack typical convulsive movements. Status epilepticus that has not responded to two medications is considered refractory status epilepticus and often requires care in an intensive care unit.

Treatment
For treatment options, see Table 25–7.

3. Febrile Seizures

Clinical Findings

A. Symptoms and Signs

Criteria for febrile seizures are (1) age 3 months to 6 years (most occur between ages 6 and 18 months), (2) fever of greater than 38.8°C, and (3) non-CNS infection. More than 90% of febrile seizures are generalized, last less than 5 minutes, and occur early in the illness causing the fever. Often the fever is not noted until after the seizure occurs. Febrile seizures occur in 2%–3% of children. Acute respiratory illnesses are most commonly associated with febrile seizures. Gastroenteritis, especially when caused by *Shigella* or *Campylobacter*, and urinary tract infections are less common causes. Roseola infantum is a rare but classic cause. One study implicated viral causes in 86% of cases. HHV-6 and HHV-7 are common causes for febrile status epilepticus, both accounting for one-third of cases. Febrile seizures rarely (1%–3%) evolve to recurrent unprovoked seizures (epilepsy) in later childhood and adult life (risk is increased two- to fivefold compared with children who do not have febrile seizures). The chance of later epilepsy is higher if the febrile seizures have complex features, such as duration longer than 15 minutes, more than one seizure in the same day, or focal features. Other predictive factors are an abnormal neurologic status preceding the seizures (eg, cerebral palsy or mental retardation), early onset of febrile seizure (before age 1 year), and a family history of epilepsy. Even with adverse factors, the risk of epilepsy after febrile seizures is still only in the range of 15%–20%, although it is increased if more than one risk factor is present. Recurrent febrile seizures occur in 30%–50% of cases. Therefore, families should be prepared to expect more seizures. In general, recurrence of febrile seizures does not worsen the long-term outlook.

B. Diagnostic Evaluation

The child with a febrile seizure must be evaluated for the source of the fever, in particular to exclude CNS infection. Routine studies such as serum electrolytes, glucose, calcium, skull radiographs, or brain imaging studies are seldom helpful unless warranted based on clinical history or suspicion of abuse. History and the examination should guide the work-up and any treatment amenable underlying infection should be addressed. Meningitis and encephalitis must be considered. Signs of meningitis (eg, bulging fontanelle, stiff neck, stupor, and irritability) may be absent, especially in a child younger than age 18 months.

C. Lumbar Puncture

After controlling the fever and stopping an ongoing seizure, the physician must decide whether to do a lumbar puncture. The fact that the child has had a previous febrile seizure does not rule out meningitis as the cause of the current episode. It is very important, especially in younger children, to exclude CNS infection as a source; these children are not classified as having a febrile seizure. A recent study demonstrated that 96% of children with febrile status epilepticus who received an LP had less than three WBC in the CSF. Therefore, seizure should not be an acceptable explanation for elevated cells in the CSF. Although the yield is low, a lumbar puncture should probably be considered done if the child is younger than age 18 months, and has been pretreated with antibiotics or is under-immunized. Certainly any child with meningeal signs fever and seizure should have an examination of their CSF. Occasionally observation in the emergency department for several hours obviates the need for a lumbar puncture, but in general one should have a low threshold for performing this potentially life-saving test.

D. EEG

EEG is rarely useful. An EEG may be considered if the febrile seizure is complicated, focal, or otherwise unusual, but has little predictive value. In uncomplicated childhood febrile seizures, the EEG is usually normal. If performed, the EEG should be done at least a week after the illness to avoid transient changes due to fever or the seizure itself. In older children, 3-Hz spike-wave discharges, suggestive of a genetic propensity to epilepsy, may occur. In the young infant, EEG findings seldom aid in assessing the chance of recurrence of febrile seizures or in long-term prognosis. Thus, EEG is not recommended for the child with simple febrile seizures.

Treatment

Prophylactic anticonvulsants are not recommended after a febrile seizure. Only phenobarbital and valproic acid have demonstrated efficacy in preventing febrile seizures; phenytoin and carbamazepine have been shown to be ineffective. Newer antiepileptic drugs have not been studied. Diazepam started at the first onset of fever for the duration of the febrile illness (0.5 mg/kg two or three times per day orally or rectally) may be effective but will sedate a child and possibly complicate the evaluation for a source of the fever. Prophylactic diazepam is also limited by the fact that a seizure is often the first evidence of fever associated with an acute illness. Diastat (rectal diazepam gel) can be used to prevent febrile status epilepticus in the child with a prolonged febrile seizure (one lasting over 5 minutes), often the greatest concern.

Measures to control fever such as sponging or tepid baths, antipyretics, and the administration of antibiotics for proven bacterial illness are reasonable but unproven to prevent recurrent febrile seizures.

Prognosis

Simple febrile seizures do not have any long-term adverse consequences. As noted earlier, there is only a small increase in the risk of developing epilepsy. Cognitive function is not significantly different from that of siblings without febrile seizures.
Hughes JR: Benign epilepsy of childhood with centrotemporal spikes (BECTS): to treat or not to treat, that is the question. Epilepsy Behav 2010;19:197–203 [PMID: 20797913].

**SLEEP DISORDERS**

Sleep disorders can originate from abnormalities within the respiratory system, the neurologic system and the coordination (or lack thereof) between these two systems. In order to understand abnormal sleep, one must understand normal sleep, which changes as the child develops. Sleep and its development are reviewed in Chapter 3. Chapter 3 also discusses behavioral considerations in the treatment of sleep disorders. Respiratory abnormalities that are associated with sleep such as obstructive sleep apnea are described in Chapter 19. This discussion focuses on neurologic features of several sleep disorders affecting children.

1. **Narcolepsy**

Narcolepsy, a primary disorder of sleep, is characterized by chronic, inappropriate daytime sleep that occurs regardless of activity or surroundings and is not relieved by increased sleep at night. One half of individuals affected by narcolepsy experience their initial symptoms in childhood. Of children with narcolepsy, 4% are under age 5, 18% are younger than age 10, and 60% are between puberty and their late teens.

Additional symptoms are cataplexy, hypnagogic and/or hypnopompic hallucinations (visual or auditory), and sleep paralysis. Cataplexy is a transient partial or total loss of muscle tone, often triggered by laughter, or other heightened emotional states. Consciousness is preserved during these spells, which can last several minutes in duration. Most patients with narcolepsy will develop cataplexy (60%–90%). Hypnagogic hallucinations are intense visual or auditory hallucinations noted while falling asleep, whereas hypnopompic hallucinations occur while waking from sleep. Sleep paralysis is a brief loss of voluntary muscle control typically occurring at sleep-wake transitions and lasting for minutes.

Abnormally short latency between sleep onset and transition into rapid eye movement (REM) sleep occurs in subjects with narcolepsy. The first cycle of REM sleep usually occurs after 80–100 minutes in normal children. Nocturnal polysomnography and Multiple Sleep Latency Testing (MSLT) can demonstrate abnormal REM latency and are used to diagnose narcolepsy. Human leukocyte antigen (HLA) subtypes DQB1*0602 and DRB1*1501 are associated with narcolepsy, as well as absence of a hypothalamic neuropeptide, hypocretin, which can be measured in CSF. Sleep hygiene and behavior modification are used to treat patients with narcolepsy. In general, medications used
for the treatment of narcolepsy in children are off label. CNS stimulants such as amphetamine mixtures are typically used to treat excessive daytime sleepiness. Modafinil and sodium oxybate are an effective treatment in adults; controlled studies in children are lacking. Cataplexy responds to fluoxetine, clomipramine, or sodium oxybate.

2. Benign Neonatal Sleep Myoclonus
Benign neonatal sleep myoclonus is characterized by myoclonic jerks, usually bilateral and synchronous, which occur only during sleep and stop abruptly when the infant is aroused. It is a benign condition that is frequently confused with epileptic seizures. Onset is typically in the first 2 weeks of life and resolves spontaneously in the first months of life, although these may occur as late as 10 months. Clusters of jerks may last from a few seconds up to 20 minutes.

3. Nocturnal Frontal Lobe Epilepsy
Nocturnal frontal lobe epilepsy (NFLE) is characterized by paroxysmal arousals from NREM sleep with hypermotor seizures characterized by bizarre stereotyped hyperkinetic of dystonic motor movements lasting up to 5 minutes. NFLE is a heterogeneous disorder which includes both sporadic and familial forms. Lack of definitive epileptiform abnormalities on EEG recordings may lead to misdiagnoses of a parasomnia, such as night terrors or somnambulism.

4. Parasomnias
Parasomnias are abnormal behavioral or physiologic events that occur in association with various sleep stages or the transition between sleeping and wakening. The parasomnias of childhood are divided into those occurring in non-REM sleep (NREM) sleep with hypermotor seizures characterized by bizarre stereotyped hyperkinetic of dystonic motor movements lasting up to 5 minutes. NFLE is a heterogeneous disorder which includes both sporadic and familial forms. Lack of definitive epileptiform abnormalities on EEG recordings may lead to misdiagnoses of a parasomnia, such as night terrors or somnambulism.

5. Restless Legs Syndrome
Restless legs syndrome refers to a feeling of needing to move the legs (dysesthesia) that often starts when resting at night. Movement of the legs temporarily relieves the symptoms, though this can interfere with the ability to fall asleep. This disorder can be familial; therefore, a detailed family history may be helpful. Occasionally, anemia (low ferritin) has been noted in adults and children with the disorder; in these cases, improvement has occurred with ferrous sulfate treatment. These are discussed in more detail in Chapter 3.

HEADACHES

The two most common causes of headaches in children are migraine and tension-type headache.

Diagnosis is based upon a thorough history and physical, excluding secondary causes such as mass or idiopathic intracranial hypertension.

Warning signs that may require further investigation include headache in a young child, new onset and worsening headache, unexplained fever, awakening with headache or vomiting, headache worse with straining or position change, posterior headaches, neurologic deficit, or neurocutaneous stigmata.

Headaches are common in children and adolescents and health providers need to recognize and differentiate the common from the more serious causes of headaches. Approximately 45% of children experience at least one debilitating headache, and up to 28% of adolescents have migraines. First, the clinician must determine if the headache is primary or secondary. Symptoms and signs are the center of evaluation; however, red flags (Table 25–8) may prompt further workup and evaluation. Correct diagnosis of headache disorders will guide treatment and management.
Clinical Findings

A. Symptoms and Signs

Based on the 2013 International Classification of Headache Disorders, 3rd Edition (beta version) (ICHD-III beta), primary headaches are divided into three major categories: migraine, tension-type, and trigeminal autonomic cephalalgias. Clinical features of migraine without aura and tension-type headache are compared in Table 25–9. Individuals with greater than 15 headaches (migraine or tension-type) per month are considered chronic, and medication overuse must be excluded. Triggers of head pain can include stress, sleep deprivation, dehydration, skipped meals, caffeine, and possibly specific foods (eg, monosodium glutamate or nitrates).

</tbody>
</table>

Trigeminal autonomic cephalalgias (or sub-category, cluster headache) are rare in children. They present as recurrent, unilateral severe headaches with autonomic dysfunction (watery eye, congestion, facial sweating, miosis, ptosis).

According to the ICHD-III beta, migraines include childhood periodic syndromes such as cyclic vomiting, abdominal migraine, and benign paroxysmal vertigo of childhood. History of these periodic syndromes may be discovered in children and adolescents with migraines. Infantile colic may also be a precursor or early manifestation of migraine.

B. Laboratory Findings

Routine laboratory testing has not been found to be helpful, though the evidence is limited. History and examination may prompt screening for general medical conditions as indicated.

C. Imaging Studies

Routine neuroimaging is not indicated for children presenting with recurrent headaches and a normal neurologic examination. Red flags as noted in Table 25–8 should at least prompt consideration of imaging. The type of imaging (CT vs MRI) depends on the urgency of evaluation (ie, acute onset severe headache vs worsening headache over 1–2 weeks). See the discussion on pediatric neuroradiologic procedures for discussion on benefits of different imaging modalities.

Differential Diagnosis

Secondary causes of headache include broad categories such as head trauma, infection, vascular, intracranial pressure changes, structural, metabolic, toxic, medication, illicit drug related, and hematologic (Table 25–10). Headaches associated with head trauma are those that start within 2 weeks of closed head injury. They can have either features of migraines or tension-type headaches. Neck pain and headache after head trauma warrant evaluation for a dissection, especially if examination is suggestive for a connective tissue disorder such as Marfans. Headaches that worsen with lying down or vomiting without nausea are concerning for increased intracranial hypertension such as IIH, sinus venous clot producing increased CSF pressure, hydrocephalus, or mass. It is worth noting that, in studies evaluating the utility of imaging in pediatric headache, up to 98% of patients with intracranial process requiring surgical intervention had an abnormal neurologic examination. Headaches that worsen with standing and improve with lying down are suggestive of low-pressure headaches caused by a tear in the dura from a preceding LP or spontaneous leak.

Medication and illicit drug ingestion and withdrawal are both culprits to secondary headaches. Steroids, vitamin A toxicity, oral contraceptives, and tetracycline
are all associated with IIH. Medications that are commonly associated with medication overuse headache include aspirin, acetaminophen, NSAIDs, triptans, and combination analgesics such as acetaminophen, butalbital, and caffeine. Other toxins such as lead, carbon monoxide, or organic solvent poisoning cannot be overlooked.

Infections both of the CNS or systemically are associated with new onset headaches. Additionally, common systemic or other focal infections may cause headaches such as viral upper respiratory infections, strep pharyngitis (especially in younger children), rhinosinusitis (sinus headache), influenza, and Lyme disease. Migraines are frequently misdiagnosed as sinus headaches and physicians should carefully obtain history of pain in the face, ears, or teeth and evaluate for signs of rhinosinusitis on either physical examination or imaging.

Any cause of hypoxia (eg, cardiac, respiratory, altitude, anemia) may cause a bifrontal throbbing headache that may be worsened with exertion, straining, or laying down. Hypercapnia causes a nonspecific headache and may be secondary to sleep apnea or other underlying metabolic or respiratory disorder.

Although eye strain and temporal mandibular joint dysfunction are rare causes of recurrent headaches, they can be simply treated; therefore, when suspected, evaluation by ophthalmology or dentistry, respectively, is indicated. Examination in temporomandibular joint dysfunction can include local pain, deviation of the mandible, jaw clicking, and limitations of chewing motion.

A thorough history and physical examination helps diagnose most of these conditions.

**Complications**

Migraines and tension-type headaches are episodic headache disorders but may transform into chronic headaches when a child has more than 15 headache days per month for three or more months. Risk factors for chronicity include psychological comorbidity, obesity, and excessive medication.

Depression and anxiety are both comorbid with headaches and are associated with increased headache burden and disability, such as school absenteeism and poor school performance. Equally, childhood psychiatric disorders also have increased rates of primary headaches. Maintaining school attendance in children with headaches is a key factor in limiting chronicity and further disability from headaches.

**Treatment**

Treatment is divided into two categories: acute/abortive and preventative. Management of headaches should emphasize the necessity for early and adequate treatment during a headache, in addition to self-management skills to reduce frequency and disability such as life-style modification and headache diaries. Pharmacologic preventative treatment can be considered if frequency or disability is significant.

**A. Acute/Abortive Treatment**

Acute treatment for pediatric migraine includes use of simple analgesics and migraine-specific medications. Any medication used to abort a headache (abortive medication) should be given as early as possible after the onset of headache. Simple analgesics include acetaminophen (15 mg/kg; max dose 650 mg) and ibuprofen (10 mg/kg; max dose 800 mg), often used as first-line therapy. The United States FDA has approved almotriptan (ages 12–17) and rizatriptan (ages 6–17). Studies have shown significant benefit for pediatric migraine using rizatriptan oral (5 mg for 20–39 kg, 10 mg for > 40 kg), almotriptan oral (6.25 or 12.5 mg), zolmitriptan nasal (5 mg > 12 y), and sumatriptan nasal (10 mg for < 40 kg, 20 mg for > 40 kg). Occasionally home treatment fails and patients may need IV medications either in an emergency department or infusion center. When a patient fails emergency room treatments, IV dihydroergotamine can be effective with nausea as the most common side effect. All medications used for abortive treatment should be used cautiously to avoid medication overuse headache.

</table>
Simple analgesics should be limited to 2–3 times per week and migraine-specific medications to less than 1–2 times per week. During a headache biobehavioral techniques include rest, relaxation, and cold/hot packs. Providing the child with a cool dark room in which to rest may provide added benefit.

**B. Prevention**

Any child with headaches should have biobehavioral management as a center point to treatment. This includes sleep hygiene (such as bedtime routine, adequate duration, and good quality of sleep), improved fluid intake, elimination of caffeine, regular nutritional meals, regular exercise and stretching, and stress management. Preventative treatment can be considered in individuals with headache frequency of one or more per week. Treatments should be chosen by optimizing wanted side-effects and minimizing unwanted side effects (eg, using topiramate in an obese child given its side-effect of weight loss).

Treatments are categorized into antiepileptic (eg, topiramate, valproic acid, levetiracetam), antihypertensive (eg, β-blockers, calcium channel blockers), antidepressants (eg, amitriptyline), antihistamine/antiserotonergic (eg, cyproheptadine), and nutraceuticals. Only small randomized double-blinded or open-label studies have tested these agents. The only FDA-approved migraine preventive medication in pediatric populations is topiramate for migraines in adolescents 12–17 years old.

Topiramate, amitriptyline, and cyproheptadine are the most commonly prescribed medications for pediatric headache. If topiramate is started slowly and at low doses, cognitive side effects can be avoided. Peripheral tingling is uncommon and when present usually can be tolerated by most children. Decreased appetite and weight loss should be monitored at routine appointments. Amitriptyline is usually dosed at nighttime given its side effect of sedation, in addition to other common side effects including constipation, dry mouth, and prolonged QT (typically at higher doses). Cyproheptadine is a good medication to use in younger children given its small side-effect profile of primary increased appetite and sedation. Divalproex sodium has not shown efficacy and side effects including weight gain, tremor, hair loss, and teratogenicity warrant caution in adolescent female patients.

Cognitive behavioral therapy is efficacious in significantly decreasing migraine frequency and disability in youth. Coenzyme q10 and magnesium oxide have shown some efficacy in childhood migraine. They may be a useful option for children with low frequency headache, low disability, or individuals who favor nonpharmaceutical options.

**Prognosis**

From the few studies regarding long-term prognosis in adolescents presenting with migraines, approximately 25%–40% of adolescents will have remission of migraine symptoms, 40%–50% have persistence, and 20%–25% convert to tension-type headache. Of those with TTH, 20% convert to migraine. Headache severity at diagnosis is thought to be predictive of headache outcome in the long term.
Interestingly, multiple medications have been associated with IIH, including tetracycline, steroids, and retinol.

**Clinical Findings**

Presenting features include new or chronic positional headache, vomiting, pulsatile tinnitus, papilledema, and diplopia. Later findings may include visual loss and optic atrophy. Visual symptoms are commonly secondary to transient visual obscurations (TVOs), which are transient (< 1 minute) and reversible alterations of vision in these patients. This must be distinguished from visual field anomalies, which can be permanent. IIH is characterized by increased intracranial pressure as documented by a lumbar puncture performed in the lateral decubitus position in the absence of an identifiable intracranial mass, infection, metabolic derangement, or hydrocephalus.

**Differential Diagnosis**

The cause of IIH is usually unknown, but it has been described in association with a variety of inflammatory, metabolic, toxic, and connective tissue disorders (Table 25–11). Assessing for alternative causes of increased intracranial pressure is essential to the diagnosis. MRI (or urgent CT for critically ill patients) may reveal hydrocephalus, tumor, or abscess. MRV may demonstrate a cerebral sinovenous thrombosis (CSVT), requiring hematological evaluation and consideration of anticoagulation. As noted in Table 25–11, medications, endocrinologic disturbances, and rheumatologic anomalies may all predispose patients to IIH. Lumbar puncture is essential to the diagnosis, as it confirms the presence of increased pressure (above 180–250 mm H₂O depending on technique and anesthetic used), but also assesses for white blood cell count, glucose, and protein (looking for an infectious mimicker, such as chronic meningitis). In some inflammatory and connective tissue diseases, the CSF protein concentration may also be increased.

**Complications**

Vision loss is the main complication of IIH, as chronic papilledema may lead to permanent optic nerve damage. Vision loss usually occurs in the blind spot and/or nasal aspects of the visual field prior to affecting central vision. Headache, TVOs, cranial nerve VI palsy, and malaise are usually reversible.

**Treatment**

Treatment of IIH is aimed at correcting the identifiable predisposing condition and preventing vision loss. Sequential ophthalmologic evaluation to assess optic nerve swelling and visual fields is important. Obese patients will benefit significantly from weight loss. Some patients may benefit from the use of acetazolamide or topiramate to decrease the volume and pressure of CSF within the CNS. If a program of medical management and ophthalmologic surveillance fail, lumbo-peritoneal shunt, ventriculoperitoneal shunt, or optic nerve fenestration may be necessary to prevent irreparable visual loss and damage to the optic nerves. Dural venous stenting has limited data in adults with no randomized studies in either adults or children.

**Prognosis**

With appropriate workup and treatment, most patients recover from IIH without long-term sequela including visual outcome. Reoccurrence risk is greatest within 18 months.

CEREBROVASCULAR DISEASE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Perinatal ischemic stroke is defined as strokes occurring in neonates younger than 28 days old.
- Childhood ischemic stroke occurs in children between 28 days and 18 years old.
- Neuroimaging is required to make the diagnosis of stroke.

Pediatric arterial ischemic stroke is subdivided into two categories: perinatal arterial ischemic stroke (perinatal AIS) and childhood arterial ischemic stroke (childhood AIS). Generally, perinatal AIS is defined as arterial ischemia occurring in a patient younger than age 28 days and older than 28 weeks gestation. Childhood AIS is any ischemic stroke occurring in a patient between 28 days and 18 years old.

1. Childhood Arterial Ischemic Stroke

Childhood AIS is emerging as a serious and increasingly recognized disorder, affecting 1.6 per 100,000 children per year. There are numerous adverse outcomes, which include death in 10%, neurologic deficits or seizures in 70%–75%, and recurrent ischemic stroke in up to 20%. It is essential to recognize that childhood AIS represents a neurologic emergency, for which prompt diagnosis can affect treatment considerations and outcome. Unfortunately, most pediatric AIS is not recognized until > 24 hours after onset; and treatment considerations matter most in the first few hours after stroke onset. When possible, all children who present with ischemic stroke should be transferred to a tertiary care center that specializes in pediatric stroke management. The evaluation should include a thorough history of prior illnesses, especially those associated with varicella (even in the prior 1–2 years) preceding viral infection, minor head or neck trauma, and familial clotting tendencies. A systematic search for evidence of cardiac, vascular, hematologic, or intracranial disorders should be undertaken (Table 25–12). Although many ischemic strokes are not associated with a single underlying systemic disorder, congenital heart disease is the most common predisposing condition, followed by hematologic and neoplastic disorders. In many instances the origin is multifactorial, necessitating a thorough investigation even when the cause may seem obvious. Arteriopathy is seen in as many as 80% of “idiopathic” patients, and likely confers an increased recurrence risk.

Clinical Findings

A. Symptoms and Signs

Manifestations of arterial ischemic stroke in childhood vary according to the vascular distribution to the brain structure that is involved. Because many conditions leading to childhood ischemic stroke result in emboli, multifocal neurologic involvement is common. Children may present with acute hemiplegia similarly to ischemic stroke in adults. Unilateral weakness, sensory disturbance, dysarthria, and/or dysphagia may develop over a period of minutes, but at times progressive worsening of symptoms may evolve over several hours. Bilateral hemispheric involvement may lead to a depressed level of consciousness. The patient may also demonstrate disturbances of mood and behavior and experience focal or multifocal seizures. Physical examination of the patient is aimed not only at identifying the specific deficits related to impaired cerebral blood flow, but also at seeking evidence for any predisposing disorder. Retinal hemorrhages, splinter hemorrhages in the nail beds, cardiac murmurs, rash, fever, neurocutaneous stigmata, and signs of trauma are especially important findings.

B. Laboratory Findings and Ancillary Testing

In the acute phase, certain investigations should be carried out emergently with consideration of treatment options. This should include complete blood count, complete metabolic panel, serum or urine pregnancy test, disseminated intravascular coagulation (DIC) panel, fibrin split products, erythrocyte sedimentation rate, C-reactive protein, prothrombin time/partial thromboplastin time, anti-factor Xa activity, chest radiography, ECG, urine toxicology, and imaging (see the following section). Subsequent studies can be carried out systemically, with particular attention to disorders involving the heart, blood vessels, platelets, red cells, hemoglobin, and coagulation proteins. Twenty to fifty percent of pediatric ischemic stroke patients will have a prothrombotic state. Additional laboratory tests for systemic disorders such as vasculitis, mitochondrial disorders, and metabolic disorders are sometimes indicated.

Examination of CSF is indicated in patients with fever, nuchal rigidity, or altered mental status when the diagnosis of intracranial infection requires exclusion. Lumbar puncture may be deferred until a neuroimaging scan (excluding brain abscess or a space-occupying lesion that might contraindicate lumbar puncture) has been obtained. In the absence of infection, rheumatologic disease or intracranial subarachnoid hemorrhage, CSF examination is rarely helpful in defining the cause of the cerebrovascular disorder.

EEG may help in patients with severely depressed consciousness. ECG and echocardiography are useful both in the diagnostic approach to the patient and in ongoing monitoring and management, particularly when hypotension or cardiac arrhythmias complicate the clinical course or when the stroke is thought to be embolic in nature.

C. Imaging

CT and MRI scans of the brain are helpful in defining the extent of cerebral involvement with ischemia or hemorrhage. CT scans may be normal within the first 12–24 hours of an ischemic stroke and are more useful to exclude intracranial hemorrhage. This information may be helpful in the early stages of management and in the decision to treat with anticoagulants. Given the high incidence of ischemic stroke mimickers in the pediatric population (migraine with aura, Todd’s paralysis, encephalitis, etc.), urgent MRI with diffusion-weighted imaging (DWI) is increasingly used in pediatric stroke centers.

Vascular imaging of the head and neck is an important part of pediatric ischemic stroke management and may include CTA, MRA, or conventional angiography. In studies in which both MRA and cerebral angiography have been used, up to 80% of patients with idiopathic childhood-onset arterial ischemic stroke have demonstrated a vascular abnormality. Vascular imaging is helpful in diagnosing disorders such as transient cerebral arteriopathy, arteriopathy associated with sickle cell disease, moyamoya disease, arterial dissection, aneurysm, fibromuscular dysplasia, and vasculitis. Studies have demonstrated that patients with vascular abnormalities on MRA or conventional angiography have a much greater recurrence risk than patients with normal vessels. When vessel imaging is performed, all major vessels should be studied from the aortic arch. With evidence of fibromuscular dysplasia in the intracranial or extracranial vessels, renal arteriography is indicated.

Differential Diagnosis

Patients with an acute onset of neurologic deficits must be evaluated for other disorders that can cause focal neurologic deficits. Hypoglycemia, prolonged focal seizures, a prolonged postictal paresis (Todd’s paralysis), acute disseminated encephalomyelitis (ADEM), meningitis, hemorrhagic stroke, encephalitis, hemiplegic migraine, ingestion, and brain abscess should all be considered. Migraine with focal neurologic deficits may be difficult to differentiate initially from ischemic stroke. Occasionally, the onset of a neurodegenerative disorder (eg, adrenoleukodystrophy or mitochondrial disorder) may begin with the abrupt onset of seizures and focal neurologic deficits. The possibility of drug abuse and other toxic exposures must be investigated diligently in any patient with acute mental status changes.

Treatment

The initial management of ischemic stroke in a child is aimed at providing support for pulmonary, cardiovascular, and
renal function. Patients should be administered oxygen and are usually monitored in an intensive care setting. Typically, maintenance fluids without glucose are indicated to augment vascular volume. Pyrexia should be treated aggressively. Specific treatment of ischemic stroke, including blood pressure management, fluid management, and anticoagulation measures, depends partly on the underlying pathogenesis. Meningitis and other infections should be treated. Sickled cell patients require hematologists to perform urgent exchange transfusion and most patients will require chronic transfusions after hospital discharge. Moyamoya is usually treated with surgical revascularization, while patients with vasculitis are often given anti-inflammatory therapy, such as steroids.

In most idiopathic cases of childhood ischemic stroke, anticoagulation or aspirin therapy is indicated. The Royal College of Physicians Pediatric Ischemic Stroke Working Group recommends aspirin, 5 mg/kg daily, as soon as the diagnosis is made. Aspirin use appears safe but the American Heart Association (AHA) recommends yearly flu-shots and close monitoring for Reye syndrome in pediatric patients. Other groups, such as the American College of Chest Physicians, recommend initial treatment with anticoagulants, such as low-molecular-weight heparin or unfractionated heparin, for 5–7 days (while excluding cardiac sources and dissection) and then switching to aspirin (3–5 mg/days). Recent AHA guidelines support both of these approaches. In some situations, such as arterial dissection or cardioembolic events, heparinization is usually considered. In adults with cerebrovascular thrombosis, thrombolytic agents (tissue plasminogen activator) used systemically or delivered directly to a vascular thrombotic lesion using interventional radiologic techniques has been shown to improve outcome in the appropriate patients. Although case reports exist, studies in children have not been completed. AHA guidelines recommend against the thrombolysis, outside of a clinical trial for children, while equivocating in the case of adolescents. Given the time lag to diagnosis and the lack of evidence in children, tissue plasminogen activator is currently used in less than 2% of US children with ischemic stroke. The use of tissue plasminogen activator (tPA) should be limited to practitioners who are familiar with cerebrovascular disease in children.

Long-term management requires intensive rehabilitation efforts and therapy aimed at improving the child’s language, educational, and psychological performance. Length of treatment with antithrombotic agents, such as low-molecular-weight heparin and aspirin, is still being studied and depends on the etiology. Constraint therapy may be particularly helpful in cases of hemiparesis.

**Prognosis**

The outcome of ischemic stroke in infants and children is variable. Roughly one-third may have minimal or no deficits, one-third are moderately affected, and one-third are severely affected. Underlying predisposing conditions and the vascular territory involved all play a role in dictating the outcome for an individual patient. When the ischemic stroke involves extremely large portions of one hemisphere or large portions of both hemispheres and cerebral edema develops, the patient’s level of consciousness may deteriorate rapidly, and death may occur within the first few days. In contrast, some patients may achieve almost complete recovery of neurologic function within several days if the cerebral territory is small. Seizures, either focal or generalized, may occur in 30%–50% of patients at some point in the course of their cerebrovascular disorder. Recurrence is up to 14%, and is more prominent in some conditions, such as protein C deficiency, lipoprotein (a) abnormalities, and arteriopathies. Chronic problems with learning, behavior, and activity are common. Long-term follow-up with a pediatric neurologist is indicated and if possible a multidisciplinary ischemic stroke team.

### 2. Perinatal Arterial Ischemic Stroke

Perinatal arterial ischemic stroke is more common than childhood ischemic stroke, affecting 1:3500 children. Perinatal ischemic stroke has two distinct presentations: acute and delayed. Most patients with an acute presentation develop neonatal seizures during the first week of life, usually in association with a perinatal event. The seizures in acute perinatal ischemic stroke are often focal motor seizures of the contralateral arm and/or leg. The presentation is stereotypical because of the predilection of the ischemic stroke to occur in the middle cerebral artery. The presence of diffusion-weighted abnormalities on an MRI scan confirms an acute perinatal ischemic stroke during the first week of life. Other patients present with delayed symptoms, typically with an evolving hemiparesis at an average of 4–8 months. These patients are termed "presumed perinatal arterial ischemic stroke.”

Acute treatment of a perinatal ischemic stroke is usually limited to neonates with seizures. Unless an embolic source is identified, aspirin and anticoagulation are almost never prescribed. Management is based on supportive care, identification of comorbid conditions, and treatment of seizures. In acute perinatal ischemic stroke, treatable causes such as infection, cardiac embolus, metabolic derangement, and inherited thrombophilia must be ruled out. In appropriate cases, echocardiography, thrombophilia evaluation, and lumbar puncture are indicated. Supportive management focuses on general measures, such as normalizing glucose levels, monitoring blood pressure, and optimizing oxygenation.

Long-term management of perinatal ischemic stroke usually starts with identifying risk factors, which might include coagulation disorders, cardiac disease, drugs, and dehydration. Although prothrombotic abnormalities with
the best evidence of association are factor V Leiden, protein C deficiency, and high lipoprotein (a), many practitioners perform an extensive hematologic workup. Maternal risk factors such as infertility, antiphospholipid antibodies, placent al infection, premature rupture of membranes, and cocaine exposure are all independently associated with perinatal ischemic stroke. The prognosis for children who sustain perinatal ischemic strokes has been considered better than for children or adults with ischemic strokes, presumably because of the plasticity of the neonatal brain. The range of cognitive and motor outcomes after perinatal stroke is broad. Twenty to forty percent of patients who experience perinatal ischemic strokes are neurologically normal. Motor impairment affects about 40%–60% of patients and is predominantly hemiplegic cerebral palsy. In acute presentations, MRI can be predictive of motor impairment, as descending corticospinal tract diffusion-weighted MRI signal is associated with a higher incidence of hemiplegia. Language delays, behavioral abnormalities, and cognitive deficits are seen in up to 55% of infants who experience perinatal ischemic strokes. Patients are also at an increased risk for seizures. Ischemic stroke recurs in 3% of neonates and is usually associated with a prothrombotic abnormality or an underlying illness, such as cardiac malformation or infection. Given the low incidence of recurrence, long-term management is largely rehabilitative, including constraint therapies.

CONGENITAL MALFORMATIONS OF THE NERVOUS SYSTEM

Malformations of the nervous system occur in 3% of living neonates and are present in 40% of infants who die in the first year of life. Structural malformation of the CNS may result from a variety of causes, including infectious, toxic, genetic, metabolic, and vascular insults. The specific type of malformation that results from such insults depends more on the gestational period during which the insult occurs than on the specific cause. The period of induction, days 0–28 of gestation, is the period during which the neural plate appears and the neural tube forms and closes. Insults during this phase can result in a major absence of neural structures, such as anencephaly, or in a defect of neural tube closure, such as spina bifida, meningocele, or encephalocele. Cellular proliferation and migration characterize neural development that occurs from 12–20 weeks gestation. During this period, lissencephaly, pachygryria, agryria, and agenesis of the corpus callosum (ACC) may arise depending on the type of developmental disruption.

1. Abnormalities of Neural Tube Closure

Defects of neural tube closure constitute some of the most common congenital malformations affecting the nervous system, occurring in 1:1000 live births prior to the introduction of folate supplementation (which decreased incidence by 50%–75%). Up to 6% of fetuses with isolated spinal cord defects have an associated chromosomal abnormality (typically Trisomy 13 or 18), which should be screened for upon identification of the defect. Spina bifida with associated myelomeningocele or meningocele is commonly found in the lumbar region. Depending on the extent and severity of the involvement of the spinal cord and peripheral nerves, lower extremity weakness, bowel and bladder dysfunction, and hip dislocation may be present. Delivery via cesarean section followed by early surgical closure of meningoceles and meningo(myelo)celes is usually indicated. Additional treatment is necessary to manage chronic abnormalities of the urinary tract, orthopedic abnormalities such as kyphosis and scoliosis, and paresis of the lower extremities. Hydrocephalus is very common and usually requires ventriculoperitoneal shunting. For selected patients, pre-natal repair has been shown to reduce the need for VP shunt at one year and result in improved motor function at 30 months of age, though pregnancy and delivery-related complications were higher. This is a promising option for patients who meet the surgical criteria.

Diagnosis & Prevention

In general, the diagnosis of neural tube defects is obvious at the time of birth. The diagnosis may be strongly suspected prenatally on the basis of ultrasonographic findings and the presence of elevated a-fetoprotein and acetylcholinesterase in the amniotic fluid. All women of childbearing age should take prophylactic folate, which can prevent these defects and decrease the risk of recurrence by 70%.
2. Disorders of Cortical Development

Malformations of cortical development are known causes of a wide spectrum of developmental and cognitive disabilities as well as epilepsy. They are a diverse group of disorders characterized by disruption of the cortex primarily identified on MRI. Although MCD was historically classified based on stages of brain development disrupted, the field of neurogenetics has revealed over a hundred genetic mutations leading to a wide variety of overlapping structural phenotypes.

Pathogenesis

MCD can occur when one of the three primary stages of cortical development are disrupted: (1) neuronal proliferation, (2) neuronal migration, or (3) post-migrational development. The genes associated with MCD include cell-cycle regulation, angiogenesis, protein synthesis, apoptosis, cell-fate specification, cytoskeletal structure and function, neuronal migration and basement-membrane function, and inborn errors of metabolism.

Clinical Findings

Clinical presentation is variable and can be divided into those children who present early with severe neurodevelopmental deficits and diffuse MCD, and those children who present later in childhood with focal seizures or more mild developmental and intellectual disabilities and are found to have focal or multi-focal MCD.

Diffuse MCD is typically associated with a variety of signs including seizures, global developmental delay, feeding, hearing, and vision impairments, poor sleep, abnormal head size, hydrocephalus, behavior problems, autonomic dysregulation, and movement disorders. Typically, there is a higher risk for shortened lifespan in these children.

Focal MCD can be associated with normal development or mild developmental delays. Focal seizures are a common presentation. Neurodevelopmental disabilities may include mild learning disabilities and behavioral concerns (including ADHD). Sometimes, focal MCD is found incidentally when neuroimaging is done for other reasons.

Differential Diagnosis

A. Megalencephaly

Megalencephaly is an example of neuronal proliferation dysfunction and results in a brain size that is greater than three standard deviations above the mean. On MRI megalencephaly can be associated with normal cortical development, polymicrogyria, and hemimegalencephaly. Associated neurologic outcomes can include normal development, developmental delay, intellectual disability, and seizures. There are several genes and syndromes associated including Neurofibromatosis 1.

B. Lissencephaly and Subcortical Band Heterotopia

Lissencephaly is an example of abnormal migration and increased apoptosis. This severe malformation of the brain is characterized by a smooth cortical surface with minimal sulcal and gyral development. Lissencephalic brains have a primitive cortex with less than the normal six-layered cortical mantle. The pattern of pachygyria (thick gyri) and agyria (absence of gyri) may vary in an anterior to posterior gradient and help guide genetic diagnosis. Patients with lissencephaly usually have severe neurodevelopmental delay, microcephaly, and seizures (including infantile spasms), although there is significant phenotypic heterogeneity. These disorders are autosomal recessive and X-linked. LIS1 mutations on chromosome 17 are sometimes associated with dysmorphic features (Miller-Dieker syndrome). Mutations in the RELN gene result in a lissencephaly with severe hippocampal and cerebellar hypoplasia. X-linked syndromes involving mutations in DCX and ARX (associated with ambiguous genitalia) affect males with lissencephaly and females with band heterotopias or ACC. Lissencephaly with hydrocephalus, cerebellar malformations, or muscular dystrophy may occur in Walker-Warburg syndrome (POMT1 mutations and others), Fukuyama muscular dystrophy (FKTN mutation), and muscle-eye-brain disease (POMGnT1 mutation). It is particularly important to identify these syndromes not only because clinical tests are available, but also because of their genetic implications. Lissencephaly may be a component of Zellweger syndrome, a peroxisomal disorder with elevated concentrations of very-long-chain fatty acids in the serum. No specific treatment for lissencephaly is available.

C. Polymicrogyria with or Without Schizencephaly

Polymicrogyria is a post-migrational disorder characterized by an overfolded and malformed cortex that can be associated with schizencephaly, diffuse, or focal, such as bilateral...
perisylvian polymicrogyria (the classic form). Patients with bilateral perisylvian polymicrogyria may have bulbar dysfunction, variable cognitive deficits, developmental delay, and epilepsy. Etiologies of polymicrogyria vary including genetic mutations, infectious, and vascular causes.

**Treatment**

Treatment of MCD center on early child development intervention and focused symptomatic treatment (eg, attention deficit, hearing impairment, physical therapy for gait abnormalities).

**3. Disorders of Cerebellum Development**

**A. Arnold-Chiari Malformations**

Arnold-Chiari malformation type I consists of elongation and displacement of the caudal end of the brainstem into the spinal canal with protrusion of the cerebellar tonsils through the foramen magnum. In association with this hindbrain malformation, minor to moderate abnormalities of the base of the skull can occur, including basilar impression (platybasia) and small foramen magnum. Arnold-Chiari malformation type I typically remains asymptomatic for years, but in older children and young adults it may cause progressive cerebellar signs (vertigo, ataxia), paresis of the lower cranial nerves or neck/posterior head pain exacerbated by straining; rarely may it present with apnea or disordered breathing. Posterior cervical laminectomy may be necessary to provide relief from symptoms.

Arnold-Chiari malformation type II consists of the malformations found in Arnold-Chiari type I plus an associated myelomeningocele. Hydrocephalus develops in approximately 90% of children with Arnold-Chiari malformation type II. These patients may also have, hydromyelia, syringomyelia, and cortical dysplasias. The clinical manifestations of Arnold-Chiari malformation type II are most commonly caused by the associated hydrocephalus and meningocele. In addition, dysfunction of the lower cranial nerves may be present. Up to 25% of patients may have epilepsy, likely secondary to the cortical dysplasias. Higher lesions of the thoracic or upper lumbar cord are associated with mild intellectual disability in about half of patients, while over 85% of patients with lower level lesions have normal intelligence quotients (IQs).

Arnold-Chiari malformation type III is characterized by herniation of the cerebellum through the foramen magnum with associated cervical spinal cord defect. Hydrocephalus is extremely common with this malformation.

**B. Dandy-Walker Syndrome**

Despite being described over a century ago, the exact definition of the Dandy-Walker syndrome is still debated. Classically, it is characterized by aplasia of the vermis, cystic enlargement of the fourth ventricle, and rostral displacement of the tentorium. Although hydrocephalus is usually not present congenitally, it develops within the first few months of life. Ninety percent of patients who develop hydrocephalus do so by age 1 year.

On physical examination, a rounded protuberance or exaggeration of the cranial occiput often exists. In the absence of hydrocephalus and increased intracranial pressure, few physical findings may be present to suggest neurologic dysfunction. An ataxic syndrome occurs in fewer than 20% of patients and is usually late in appearing. Many long-term neurologic deficits result directly from hydrocephalus. CT or MRI scanning of the head confirms diagnosis of Dandy-Walker syndrome. Treatment is directed at the management of hydrocephalus.

**4. Agenesis of the Corpus Callosum**

Agenesis of the corpus callosum (ACC), once thought to be a rare cerebral malformation, is more frequently diagnosed with modern neuroimaging techniques, occurring in 1:4000 births. There does not appear to be a single cause of this malformation. Rather, multiple single and muti-gene mutations have been associated. An underlying genetic cause can be found in up to 45% of cases. It has been found in X-linked conditions, such as ARX mutations (lissencephaly and ambiguous genitalia), recessive conditions such as Andersen syndrome (neuropathy and dementia), and polygenic conditions such as Aicardi syndrome (chorioretinal lacunae, infantile spasms, skeletal abnormalities). No specific clinical picture is typical of ACC, although many patients have seizures, developmental delay, microcephaly, or eurobehavioral problems (autism, difficulties with social interactions). Interestingly, the malformation may be found coincidentally by neuroimaging studies in otherwise normal patients.

**5. Hydrocephalus**

Hydrocephalus is an increased volume of CSF with progressive ventricular dilation. In communicating hydrocephalus, CSF circulates through the ventricular system and into the subarachnoid space without obstruction. In noncommunicating hydrocephalus, an obstruction blocks the flow of CSF within the ventricular system or blocks the egress of CSF from the ventricular system into the subarachnoid space. A wide variety of disorders, such as hemorrhage, infection, tumors, and congenital malformations, may play a causal role in the development of hydrocephalus. Clinical features of hydrocephalus include macrocephaly, an excessive or rapid head growth, irritability, bulging or full fontanelle, vomiting, loss of appetite, impaired upgaze (known as “sun setting” phenomenon), impaired extraocular movements, hypertonia of the lower extremities, and generalized hyperreflexia. Without treatment, optic atrophy may occur. In infants, papilledema may not be present, whereas older children with closed cranial sutures can eventually develop
swelling of the optic disk. Hydrocephalus can be diagnosed on the basis of the clinical course, findings on physical examination, and CT or MRI scan.

Treatment of hydrocephalus is directed at providing an alternative outlet for CSF from the intracranial compartment. The most common method is ventriculoperitoneal shunting. Other treatment should be directed, if possible, at the underlying cause of the hydrocephalus.

ABNORMAL HEAD SIZE

Bone plates of the skull have almost no intrinsic capacity to enlarge or grow. Unlike long bones, they depend on extrinsic forces to stimulate new bone formation at the suture lines. Although gravity and traction on bone by muscle and scalp probably stimulate some growth, the single most important stimulus for head growth during infancy and childhood is brain growth. Therefore, accurate assessment of head growth is one of the most important aspects of the neurologic examination of young children. A head circumference that is two standard deviations above or below the mean for age requires investigation and explanation.

1. Craniosynostosis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Abnormal head shape.
▶ When craniosynostosis occurs with other dysmorphologies, it is considered syndromic craniosynostosis.

Craniosynostosis, or premature closure of cranial sutures, is usually sporadic and idiopathic occurring in 1 in 2000 live births.

Clinical Findings

Both idiopathic and genetic etiologies occur in children with craniosynostosis. Syndromic children, that is, those with other physical anomalies, are more likely to have a genetic etiology. For example, Apert syndrome and Crouzon disease are associated with abnormalities of the digits, extremities, and heart, as well as craniosynostosis. An interdisciplinary approach is commonly required given the numerous other systems possibly involved including learning and development, oral health, visual and ocular abnormalities, hearing and middle ear abnormalities, and speech and language development. Craniosynostosis may be associated with an underlying metabolic disturbance such as hyperthyroidism and hypophosphatasia.

Differential Diagnosis

The most common form of craniosynostosis involves the sagittal suture and results in scaphocephaly, an elongation of the head in the anterior to posterior direction. Premature closure of the coronal sutures causes brachycephaly, an increase in cranial growth from left to right. Unless many or all cranial sutures close prematurely, intracranial volume will not be compromised, and the brain’s growth will not be impaired. Closure of only one or a few sutures will not cause impaired brain growth or neurologic dysfunction.

A common complaint is abnormal head shape secondary to positional plagiocephaly due to supine sleep position, not from occipital lambdoid suture craniosynostosis. Repositioning the head during naps (eg, with a rolled towel under one shoulder), and “tummy time” when awake are remedies. Rarely is a skull film or consultation necessary to rule out craniosynostosis. Most positional nonsynostotic plagiocephaly resolves by age 2 years.

Treatment

Management of craniosynostosis is directed at preserving normal skull shape and consists of excising the fused suture and applying material to the edge of the craniectomy to prevent reossification of the bone edges. The best cosmetic effect on the skull is achieved when surgery is performed during the first 6 months of life. Inter-disciplinary team approach to manage all systems affected is essential in providing the best neurologic and psychological outcomes.

2. Microcephaly

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Head circumference more than two standard deviations below the mean for age and sex.
▶ Nearly always associated with developmental delay and learning difficulties.
Microcephaly is defined as a head circumference more than two standard deviations below the mean for age and sex. More important than a single head circumference measurement is the rate or pattern of head growth over time. Head circumference measurements that progressively drop to lower percentiles with increasing age are indicative of a process or condition that has impaired the brain’s capacity to grow. Primary microcephaly is present at birth and secondary microcephaly develops postnatally. The causes of microcephaly are numerous. Some examples are listed in Table 25–13.

### Clinical Findings

#### A. Symptoms and Signs

Head circumference should be monitored at every well-child check. However, microcephaly may be discovered when the child is examined because of delayed developmental milestones or neurologic problems, such as seizures or spasticity. There may be a marked backward slope of the forehead (as in familial microcephaly) with narrowing of the bitemporal diameter. The fontanelle may close earlier than expected, and sutures may be prominent. Abnormal dermatoglyphs (neurocutaneous marks) may be present when the injury occurred before 19 weeks’ gestation. Parents’ heads may need measurement to rule out a rare dominantly inherited familial microcephaly. Eye, cardiac, and bone abnormalities may also be clues to congenital infection.

#### B. Laboratory Findings

Laboratory findings vary with the cause. In the newborn, IgM antibody titers for toxoplasmosis, rubella, CMV, herpes simplex virus, and syphilis and urine culture for CMV may be assessed for sign of congenital infection. Genetic testing can be targeted based on history and physical examination. Genetic screening tests may be considered such as array comparative genomic hybridization (CGH) or karyotyping. Most metabolic disorders present either as congenital syndromic microcephaly (ie, dysmorphisms present on examination) or with postnatal microcephaly and global developmental delay. Nonsyndromic microcephaly presenting at birth may be due to maternal PKU (maternal serum with elevated phenylalanine), phosphoglycerate dehydrogenase deficiency (disorder of L-serine biosynthesis), or Amish lethal microcephaly (elevated urine alpha-ketoglutaric acid).

#### C. Imaging Studies

CT or MRI scans may aid in diagnosis and prognosis. These studies may demonstrate calcifications, malformations, or atrophic patterns that suggest specific congenital infections or genetic syndromes. Plain skull radiographs are of limited value. MRI is most helpful in definitive diagnosis, prognosis, and genetic counseling.

### Differential Diagnosis

Common forms of craniosynostosis involving sagittal, coronal, and lambdoidal sutures are associated with abnormally shaped heads but do not cause microcephaly. Recognizing treatable causes of undergrowth of the brain such as hypopituitarism or hypothyroidism and severe protein-calorie undernutrition is critical so that therapy can be initiated as early as possible. Refer to Table 25–13 for examples of causes of microcephaly.

### Treatment & Prognosis

Genetic counseling should be offered to the family of any infant with significant microcephaly. Many children with microcephaly are developmentally delayed. The notable exceptions are found in cases of hypopituitarism (rare) or familial autosomal dominant microcephaly. Individuals may need screening for vision and hearing abnormalities as well as supportive therapies for developmental delay.
3. Macrocephaly

A head circumference more than two standard deviations above the mean for age and sex denotes macrocephaly. Rapid head growth rate suggests increased intracranial pressure, most likely caused by hydrocephalus, extra-axial fluid collections, or neoplasms. Macrocephaly with normal head growth rate suggests familial macrocephaly or true megalencephaly, as might occur in neurofibromatosis. Other causes and examples of macrocephaly are listed in Table 25–14.

Differential Diagnosis

A. Catch-Up Growth

This can be seen when a neurologically intact preterm infant has rapid head enlargement in the first weeks of life. As the expected normal size is reached, head growth slows and then resumes a normal growth pattern.

B. Familial Macrocephaly

This condition may exist when another family member has an unusually large head with no signs or symptoms referable to such disorders as neurocutaneous dysplasias (especially neurofibromatosis) or cerebral gigantism (Sotos syndrome), or when there are no significant mental or neurologic abnormalities in the child.

C. Hydrocephalus

See section on Congenital Malformations of the Nervous System.

Other causes of macrocephaly are dependent on the etiology such as metabolic or genetic causes.

Clinical Findings

Clinical and laboratory findings vary with the underlying process. In neonates and young infants, ultrasound can be used to evaluate for subdural effusions, hydrocephalus, hydranencephaly, and cystic defects. A surgically or medically treatable condition must be ruled out. Thus, the first decision is whether and when to perform an imaging study.

A. Imaging Studies

An imaging study is necessary if signs or symptoms of increased intracranial pressure are present. If the fontanelle is open, cranial ultrasonography can assess ventricular size and diagnose or exclude hydrocephalus. CT or MRI scans are used to define any structural cause of macrocephaly and to identify an operable disorder. Even when the condition is untreatable (or does not require treatment), the information gained may permit more accurate diagnosis and prognosis, guide management and genetic counseling, and serve as a basis for comparison should future abnormal cranial growth or neurologic changes necessitate a repeat study.

NEUROCUTANEOUS DYSPLASIAS

Neurocutaneous dysplasias are diseases of the neuroectoderm and sometimes involve endoderm and mesoderm. Birthmarks and later appearing skin growths suggest a need to look for brain, spinal cord, and eye disease. Hamartomas (benign tumors that are histologically normal tissue growing abnormally rapidly or in aberrant sites) are common.
The most common dysplasias are inherited autosomal dominantly. Benign and even malignant tumors may develop in these conditions.

1. Neurofibromatosis Type 1

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- More than six café au lait spots 5 mm in greatest diameter in prepubertal individuals and over 15 mm in greatest diameter in postpubertal individuals.
- Two or more neurofibromas of any type or one plexiform neurofibroma.
- Freckling in the axillary or inguinal regions.
- optic glioma.
- Two or more Lisch nodules (iris hamartomas).
- Distinctive bony lesions, such as sphenoid dysplasia or thinning of long bone with or without pseudarthroses.
- First-degree relative (parent, sibling, offspring) with neurofibromatosis type 1 by above criteria.

Neurofibromatosis is a multisystem disorder with a prevalence of 1:3000. Fifty percent of cases are due to new mutations in the **NF1** gene, which is located on chromosome 17q11.2 encoding neurofibromin. Forty percent of patients develop medical complications over their lifetime. Two or more positive criteria are diagnostic; others may appear over time. Children with six or more café au lait spots and no other positive criteria should be followed; 95% develop neurofibromatosis type 1.

**Clinical Findings**

**A. Symptoms and Signs**

The most common presenting symptoms are cognitive or psychomotor problems; 40% have learning disabilities, and 8% have intellectual disability. The history should focus on cutaneous abnormalities causing disfigurement, functional problems, or pain. Café au lait spots are seen in most affected children by age 1 year. The typical skin lesion is 10–30 mm, ovoid, and smooth-bordered. Discrete well-demarcated neurofibromas or lipomas can occur at any age. Plexiform neurofibromas are diffuse and can invade normal tissue. They are congenital and are frequently detected during periods of rapid growth. If the face or a limb is involved, there may be associated hypertrophy or overgrowth.

Clinicians should evaluate head circumference, blood pressure, vision, hearing, spine for scoliosis, and limbs for pseudarthroses. Strabismus or amblyopia dictates a search for optic glioma, a common tumor in neurofibromatosis. The eye examination should include checking for proptosis and iris Lisch nodules. The optic disk should be examined for atrophy or papilledema. Any progressive or new neurologic deficit calls for neuroimaging to rule out tumor of the spinal cord or CNS. Short stature and precocious puberty are occasional findings.

Parents should be examined in detail. Family history is important in identifying dominant gene manifestations.

**B. Laboratory Findings**

Laboratory tests are not likely to be of value in asymptomatic patients. Selected patients require brain MRI with special cuts through the optic nerves to rule out optic glioma. A common finding is hyperintense, non-mass lesions seen on T2-weighted MRI images. These “unidentified bright objects” (UBOs) often disappear with time. Hypertension necessitates evaluation of renal arteries for dysplasia and stenosis. Cognitive and school achievement testing may be indicated. Scoliosis or limb abnormalities should be studied by appropriate imaging.

**Differential Diagnosis**

Patients with McCune-Albright syndrome often have larger café au lait spots with precocious puberty, polyostotic fibrous dysplasia, and hyperfunctioning endocrinopathies. One or two café au lait spots are often seen in normal children. A large solitary café au lait spot is usually innocent.

**Complications**

Seizures, deafness, short stature, early puberty, and hypertension occur in less than 25% of patients with neurofibromatosis. Optic gliomas occur in about 15%. Although the tumor may be apparent at an early age, it rarely causes functional problems and is usually nonprogressive. Patients have a slightly increased risk (5% life risk) for various malignancies. Other tumors may be benign but may cause significant morbidity and mortality because of their size and location in a vital or enclosed space, for example, plexiform neurofibromas. These “benign” infiltrating tumors can disfigure facially, impair spinal cord, renal, or pelvic-leg function, and are often difficult to treat. PET scans are helpful to detect malignant transformations (most commonly to sarcomas). Experimental trials of interferons and mTOR inhibitors (rapamycin=sirolimus) are ongoing at many centers. Strokes from NF-1 cerebral arteriopathy are rare but needs to be noted; arteriopathy of renal arteries can cause reversible hypertension in childhood.
Treatment

Genetic counseling and screening is important and the risk to siblings is 50%. The disease may be progressive, but with serious complications only occasionally seen. Patients sometimes worsen during puberty or pregnancy. Annual or semi-annual visits are important in the early detection of school problems and bony or neurologic abnormalities.

The following parameters should be recorded at each annual visit:

1. Child’s development and progress at school
2. Visual symptoms, visual acuity, and funduscopy until age 7 years (to detect optic pathway glioma, glaucoma)
3. Head circumference (rapid increase might indicate tumor or hydrocephalus)
4. Height (to detect abnormal pubertal development)
5. Weight (to detect abnormal pubertal development)
6. Pubertal development (to detect delayed or precocious puberty due to pituitary or hypothalamic lesions)
7. Blood pressure (to detect renal artery stenosis or pheochromocytoma)
8. Cardiovascular examination (for congenital heart disease, especially pulmonary stenosis)
9. Evaluation of spine (for scoliosis and underlying plexiform neurofibromas)
10. Evaluation of the skin (for cutaneous, subcutaneous, and plexiform neurofibromas)
11. Examination of other systems, depending on specific symptoms

Multidisciplinary clinics at medical centers around the United States can be excellent resources. Prenatal diagnosis is likely on the horizon, but the variability of manifestations (trivial to severe) will make therapeutic abortion an unlikely option. Chromosomal linkage studies are under way (chromosome 17q11.2). Information for lay people and physicians is available from the National Neurofibromatosis Foundation (http://www.nf.org).

3. Tuberous Sclerosis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

» At least three hypomelanotic macules, each at least 5 mm in diameter.
» Angiofibromas, ungual fibromas, intraoral fibromas.
» Shagreen patch.
» CNS manifestations: subependymal nodules, cortical dysplasias, subependymal giant cell astrocytoma.
» Cardiac rhabdomyomas and angiomyolipomas.
» Hamartomas.

Tuberous sclerosis (TS) is a dominantly inherited disease. Almost all individuals have deletions on chromosome 9 (TSC1 gene) or 16 (TSC2 gene). The gene products hamartin and tuberin have tumor-suppressing effects, therefore TS patients are more susceptible to hamartomas in many organs and brain tubers and tumors. A triad of seizures, mental retardation, and adenoma sebaceum occurs in only 33% of patients. Parents formerly thought to not harbor the gene are now being diagnosed as asymptomatic carriers.

Clinical Findings

Tuberous sclerosis has a wide spectrum of disease: asymptomatic with only skin findings to severe infantile spasms and mental retardation. Seizures in early infancy correlate with later mental retardation.

A. Symptoms and Signs (Table 25–15)

1. Dermatologic features—Skin findings bring most patients to the physician’s attention (Table 25–16). Ninety-six percent of patients have one or more hypomelanotic macules, facial angiofibromas, ungual fibromas, or shagreen (leathery orange peel) patches. Adenoma sebaceum (facial skin hamartomas) may first appear in early childhood, often on the cheek, chin, and dry sites of the skin where acne is not usually seen. Ash-leaf spots are off-white hypomelanotic macules often oval or “ash leaf” in shape and follow the dermatomes. A Wood lamp (ultraviolet light) shows the macules more clearly. The equivalent to an ash leaf spot in the scalp is poliosis (whitened hair patch). Subungual and periungual fibromas are more common in the toes. Café au lait spots are occasionally seen. Fibrous or raised plaques may resemble coalescent angiofibromas.
2. Neurologic features—Seizures are the most common and up to 20% of patients with infantile spasms have TS. Thus, any patient presenting with infantile spasms (and the parents as well) should be evaluated for this disorder. An imaging study of the CNS, such as a CT scan, may show calcified subependymal nodules; MRI may show dysmyelinating white matter lesions or cortical tubers. Virtually any kind of symptomatic seizure (eg, atypical absence, partial complex, and generalized tonic-clonic seizures) may occur. Mental retardation occurs in up to 50% of patients referred to tertiary care centers; the incidence is probably much lower in randomly selected patients. Patients with seizures are more prone to mental retardation or learning disabilities.

3. Renal lesions—Renal cysts or angiomyolipomas may be asymptomatic but can lead to outflow obstruction, conduction difficulties, and death. Chest radiographs and echocardiograms can detect these rare manifestations. Cardiac rhabdomyomas may be detected on prenatal ultrasound examination. Rhabdomyomas typically regress with age; thus, symptomatic presentations are typically in the perinatal period or infancy when rhabdomyomas are largest.

4. Cardiopulmonary involvement—Rarely cystic lung disease may occur. Rhabdomyomas of the heart may be asymptomatic but can lead to outflow obstruction, conduction difficulties, and death. Chest radiographs and echocardiograms can detect these rare manifestations. Cardiac rhabdomyomas may be detected on prenatal ultrasound examination. Rhabdomyomas typically regress with age; thus, symptomatic presentations are typically in the perinatal period or infancy when rhabdomyomas are largest.

5. Eye involvement—Retinal hamartomas are often near the disk and usually asymptomatic.

6. Skeletal involvement—Cystic rarefactions can be found in the bones of the fingers or toes.

B. Imaging Studies and Special Tests

Plain radiographs may detect areas of thickening within the skull, spine, and pelvis, and cystic lesions in the hands and feet. Chest radiographs may show lung honeycombing. MR and CT imaging can show the virtually pathognomonic subependymal nodular calcifications, sometimes widened gyri or tubers, and brain tumors. Hypomelinated lesions may be seen with MRI. EEG should be considered in any TS patient with new-onset spells concerning for seizures.

Treatment

Therapy is as indicated by underlying disease (eg, seizures and tumors of the brain, kidney, and heart). Skin lesions on the face may need dermabrasion or laser treatment. Genetic counseling emphasizes identification of the carrier. The risk of appearance in offspring if either parent is a carrier is 50%. The patient should be seen annually for counseling and reexamination in childhood. Identification of the chromosomes (9,16; TSC1 and TSC2 genes) may in the future make intrauterine diagnosis possible. Treatment of refractory epilepsy may lead to surgical extirpation of epileptiform tuber sites.

Recent research has suggested the “mammalian target of rapamycin” (mTOR) inhibitors (eg, rapamycin) may inhibit epilepsy in tuberous sclerosis, even shrink dysplasia/tubers, tumors, adenoma sebacea, and possibly improve learning.

4. Encephalofacial Angiomatosis (Sturge-Weber Disease)

AR, autosomal recessive; CNS, central nervous system; CSF, cerebrospinal fluid; CT, computed tomography; EEG, electroencephalogram; ERG, electroretinogram; MRI, magnetic resonance imaging; WBC, white blood cell.
Sturge-Weber disease is a sporadic neurovascular disease, which consists of a facial port wine nevus involving the upper part of the face (in the first division of cranial nerve V), a venous angioma of the meninges in the occipitoparietal regions, and choroidal angioma. The syndrome has been described without the facial nevus (rare, type III, exclusive leptomeningeal angioma).

**Clinical Findings**

**A. Symptoms and Signs**

In infancy, the eye may show congenital glaucoma, or buphthalmos, with a cloudy, enlarged cornea. In early stages, the facial nevus may be the only indication, with no findings in the brain even on radiologic studies. Focal seizures are common in infancy. Cognitive impairment, headache and migraines, and stroke-like signs are other neurologic manifestations. The characteristic cortical atrophy, calcifications of the cortex, and meningeal angiomatosis may appear with time, solidifying the diagnosis.

Physical examination may show hemiparesis on the side contralateral to the cerebral lesion. The facial nevus may be much more extensive than the first division of cranial nerve V; it can involve the lower face, mouth, lip, neck, and even torso. Hemiatrophy of the contralateral limbs may occur. Mental handicap may result from poorly controlled seizures. Late-appearing glaucoma and rarely CNS hemorrhage occur.

**B. Imaging and Special Tests**

Radiologic studies may show calcification of the cortex; CT scanning may show this much earlier than plain radiographic studies. MRI often shows underlying brain involvement.

The EEG often shows depression of voltage over the involved area in early stages; later, epileptiform abnormalities may be present focally.

**Differential Diagnosis**

The differential diagnosis includes (rare) PHACES syndrome: Posterior fossa malformation, segmental (facial) Hemangioma, Arterial abnormalities, Cardiac defects, Eye abnormalities, and Sternal (or ventral) defects; often, only portions of that list are present.

**Management & Treatment**

Early control of seizures is important to avoid consequent developmental setback. If seizures do not occur, normal development can be anticipated. Careful examination of the newborn, with ophthalmologic assessment to detect early glaucoma, is indicated. Rarely, surgical removal of the involved meninges and the involved portion of the brain may be indicated, even hemispherectomy.

5. Von Hippel-Lindau Disease (Retrocerebellar Angiomatosis)

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Retinal, central nervous, renal hemangioblastomas.
- Visceral cysts.
- Less frequently adrenal and extra-adrenal pheochromocytomas, pancreatic endocrine cancers, and endolymphatic sac tumors.

Von Hippel-Lindau disease is a rare, dominantly inherited condition with retinal and cerebellar hemangioblastomas; cysts of the kidneys, pancreas, and epididymis; and sometimes renal cancers. The patient may present with ataxia, slurred speech, and nystagmus due to a hemangioblastoma of the cerebellum or with a medullary spinal cord cystic hemangioblastoma. Retinal detachment may occur from hemorrhage or exudate in the retinal vascular malformation. Rarely a pancreatic cyst or renal tumor may be the presenting symptom.

The diagnostic criteria for the disease are a retinal or cerebellar hemangioblastoma with or without a positive family history, intra-abdominal cyst, or renal cancer.

CENTRAL NERVOUS SYSTEM DEGENERATIVE DISORDERS OF INFANCY & CHILDHOOD

The CNS degenerative disorders of infancy and childhood are characterized by developmental arrest and loss, usually progressive but at variable rates, of cognitive, motor, and visual functioning (Tables 25–16). Seizures are common especially in those with gray matter involvement. Symptoms and signs vary with age at onset and primary sites of involvement.

These disorders are fortunately rare. An early clinical pattern of decline often follows normal early development. Referral for sophisticated biochemical testing is usually necessary before a definitive diagnosis can be made. Patients with metachromatic leukodystrophy, Krabbe disease, and adrenoleukodystrophy are candidates for bone marrow transplantation. Treatment of some lysosomal storage diseases, such as Gaucher disease, with enzyme replacement therapy (ERT) has shown promising results.

ATAXIAS OF CHILDHOOD

Ataxia is defined as difficulty coordinating voluntary movements of the limbs and/or trunk.

Ataxia is most commonly due to cerebellar dysfunction but can be caused by abnormalities at almost any component of the nervous system.

Acute, episodic, and subacute/chronic ataxias have different etiologies, which can guide the evaluation, management, and outcome.

A detailed history and evaluation of truncal versus limb ataxia, mental status, and eye movements can provide the most useful diagnostic points in the formulation of the differential diagnosis.

Ataxia can be divided into categories based on the chronicity of symptoms. Acute ataxia is a common reason for emergent neurologic consultation. Typically, the patient was previously healthy, without developmental delay or neurologic deficits, and then developed symptoms within 72 hours of presentation. The evaluation should include a detailed history of the anteecedent events and current symptoms, as well as a comprehensive neurologic examination. In contrast, a patient with a subacute, episodic, or chronic ataxia often has developmental delay, other neurologic deficits, or other organ system involvement. In this section, a brief overview of the most common causes of ataxia, and the evaluation and the management of each, is provided.

ACUTE ATAXIAS OF CHILDHOOD

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

» Symptoms may include sudden development of a wide-based, “drunken” gait or possibly refusal to walk.

» Families may not notice unsteady arm movements, truncal swaying, or dysarthria, but these symptoms are often present and are essential to localization.

» Serious causes such as ingestion, CNS infection, stroke, or intracranial mass lesion, must be excluded, either by clinical history/examination or with lumbar puncture and brain MRI.

» Pathogenesis

Causes of acute ataxia that require emergent evaluation include toxic ingestion, CNS infection, increased intracranial pressure due to mass lesion, trauma, and stroke. Therefore, a detailed history should assess for exposures, fever, altered mental status, irritability, persistent or recurrent headaches, developmental regression, blurry or double vision, nausea/vomiting, and other neurologic deficits.

» Clinical Findings

A thorough examination should be performed, with attention to signs suggesting a serious central nervous system disorder. Changes in mental status may suggest an ingestion, CNS infection, acute disseminated encephalomyelitis, or opsoclonus-myoclonus syndrome (OMS). The presence of papilledema or cranial nerve palsy suggests an intracranial mass lesion or hydrocephalus. The evaluation of an acutely ataxic patient can be difficult as the patient may refuse to participate due to the discomfort of being ataxic or associated mental status changes. Therefore, distinguishing between weakness, sensory loss, and ataxia can be difficult, but it is essential to localizing the lesion and making the correct diagnosis. For example, asymmetry in the examination
Infectious etiology is possible. Lumbar puncture should be performed if an inflammatory, demyelinating, or toxic etiology is possible. For children older than 3 years who presented with more than 3 days of symptoms, brain imaging demonstrated clinically urgent intracranial pathology (such as brain tumor or ADEM) in 10%–20%. Younger children and children with alternative diagnosis, such as CNS infection or Guillain-Barre syndrome. Brain MRI is typically normal, but can show T2 hyperintensities in the cerebellum. Treatment for APCA is typically supportive. Intravenous immunoglobulin (IVIg) has been used in severe cases. Steroids are not effective.

**Differential Diagnosis**

**A. Acute Postinfectious Cerebellar Ataxia**

Acute postinfectious cerebellar ataxia (APCA, also called acute cerebellar ataxia or ACA) causes approximately 40% of cases of acute ataxia and typically affects children aged 2–4 years. Clinical signs occur abruptly (over hours), evolve rapidly, and typically include unsteady gait, truncal swaying, dysmetria, tremor, or abnormal eye movements. Mental status is essentially normal, though some patients are mildly irritable. Sensation, strength, and reflex testing are normal. In 70% of patients, a prodromal illness, such as varicella, influenza, Epstein-Barr virus, or Scarlet fever, occurs within 3 weeks of onset. Diagnostic testing should include lumbar puncture and brain imaging. CSF opening pressure, protein, and glucose levels are typically normal, though a mild pleocytosis with lymphocytic predominance can be seen. Significant elevation in WBC or protein level suggests an alternative diagnosis, such as CNS infection or Guillain-Barre syndrome. Brain MRI is typically normal, but can show T2 hyperintensities in the cerebellum. Treatment for APCA is typically supportive. Intravenous immunoglobulin (IVIg) has been used in severe cases. Steroids are not effective. Physical therapy can be helpful. Most patients recover without sequelae within 8 months, though some may have neurologic sequelae.

**B. Toxic Cerebellar Syndrome**

Toxic ingestion accounts for one-third of cases of acute ataxia in children. Common substances include anticonvulsants, benzodiazepines, alcohol, marijuana, and cough syrup (dextromethorphan). Environmental agents, such as heavy metals (bismuth, mercury, and lead), can also cause ataxia. Mental status changes, nystagmus, pupillary changes, tremor, or other toxidromal symptoms may also occur. Urine toxicology screen may not detect specific medications or illicit substances. Imaging is typically normal. Therefore, a detailed history is required to guide testing for specific substances or make an empiric diagnosis. Treatment is guided by the ingested agent and requires toxicology consultation.

**C. Intracranial Mass Lesions**

Posterior fossa tumors (arising from the cerebellum or brainstem) comprise up to 60% of childhood brain tumors. Most patients experience gradual onset of progressive ataxia and clinical signs and symptoms of increased intracranial pressure, such as lethargy, headache, vomiting, or eye movement abnormalities. However, some children can present with a more rapid evolution of signs and symptoms, and even children with a large tumor and obstructive hydrocephalus can initially have only minor deficits. Therefore, any patient with a history of nocturnal headaches, nocturnal emesis, focal neurologic deficits, visual changes, or other signs concerning for mass lesion should have neuroimaging performed immediately.

**D. Posterior Circulation Stroke (Ischemic or Hemorrhagic)**

Though rare, stroke should be considered in the differential for acute ataxia, particularly if a history of neck trauma or family history of vascular or hematologic abnormalities is present. Due to the brainstem/cerebellar involvement of a posterior circulation stroke, the patient may also have significant vertigo, nausea/vomiting, nystagmus, cranial nerve palsies, hearing changes, hiccups, sensory loss, hemiparesis, or even quadriparesis. Cerebral venous sinus thrombosis should also be considered.

**E. CNS Infections—Cerebellitis, Brainstem Encephalitis, and Meningitis**

Some infectious agents, such as Listeria, varicella, and enterovirus 71, have a predilection for the brainstem and cerebellum, either via leptomeningeal involvement or direct invasion of the parenchyma. In some cases, postinfectious inflammation can be quite severe. Patients are typically quite ill and encephalopathic. Brain MRI may demonstrate cerebellar edema, which in some cases has required decompressive craniectomy.
F. Acute Demyelinating Encephalomyelitis

Ataxia can be a presenting symptom of acute demyelinating encephalomyelitis (ADEM), an immune-mediated, transient demyelinating disorder. ADEM often occurs after a viral infection or vaccination, most commonly in children aged 2–10 years. Unlike ACG, ADEM is typically associated with additional deficits, such as a dramatic change in mental status (encephalopathy), seizures, cranial nerve palsies, or extremity weakness. Refer to section “Noninfectious Inflammatory Disorders of the Central Nervous System.”

G. Sensory Ataxia

Pathology within the spinal cord, spinal nerve roots, or peripheral nerves can disrupt sensory input to the cerebellum, resulting in a sensory ataxia. Etiologies may include poliomielitis-like infections, spinal cord demyelinating process (such as ADEM, transverse myelitis, MS, or neuromyelitis optica spectrum disorder), (typically due to vitamin B12 deficiency), Guillain–Barre syndrome (GBS; also called acute inflammatory demyelinating polynuropathy, AIDP) or its variant, Miller–Fisher syndrome, or toxins. In addition to ataxia, patients typically have hypotonia or hypertonia, weakness, abnormal tendon reflexes, abnormal Romberg sign, loss of proprioception and vibratory sensation, or a high “steppage” gait. Autonomic instability or bowel/bladder dysfunction may also be notable. Diffuse or difficult to localize pain can be a predominate feature. Testing for suspected GBS should include a lumbar puncture to evaluate for elevated CSF protein with normal CSF white blood cell count, known as albuminocytologic dissociation, but early in the course, CSF can be normal in up to 50% of children. Antibodies against GQ1b may be positive in Miller–Fisher syndrome. Screening for toxins and vitamin deficiencies may be appropriate if the history is suggestive. Spine MRI may show enhancement of the nerve roots in GBS or infectious radiculoneuritis (such as Lyme disease). Posterior column lesions suggest demyelination, myelitis, or neurodegenerative changes. Nerve conduction studies and EMG may be helpful, though these are often normal during the acute period. GBS can be treated with either IVIg (2 g/kg divided over 3–5 days) or plasmapheresis, which have similar efficacy. Intravenous immunoglobulin for Guillain–Barre syndrome. Cochrane Database Syst Rev 2014;(9):CD002063 [PMID: 25238327].

H. Paraneoplastic Syndromes

Acute ataxia can occasionally be seen in OMS, sometimes called opsoclonus–myoclonus–ataxia syndrome, a rare paraneoplastic/autoimmune disorder that primarily affects young children. Proposed diagnostic criteria for OMS (rapid, multidirectional conjugate abnormal eye movements) are myoclonus (nonepileptic jerks of the face, head, or extremities) and/or ataxia, behavioral changes and/or sleep disruption, and/or neuroblastoma. Cognitive dysfunction can also be seen. Many patients do not immediately meet diagnostic criteria, and a high index of suspicion is needed to ultimately make the diagnosis.

I. Migraine with Brainstem Aura (formerly called “Basilar Migraine”)

Migraine with brainstem aura can be associated with ataxia. Most patients will have other neurologic signs and symptoms, such as vertigo, nausea/vomiting, cranial nerve dysfunction, and/or headache. Positive visual phenomenon (such as flashing lights or “zig-zag” lines) or a “marching” progression of symptoms (reflecting cortical spreading depression) can provide clues to the diagnosis of migraine. However, migraine with aura is a diagnosis of exclusion, and the initial presentation warrants a prompt workup for possible stroke.

J. Vestibular Pathology

Disturbances in the vestibular system can cause ataxia, often accompanied by dramatic vertigo, nausea/vomiting, eye movement abnormalities (such as skew deviation or nystagmus), or hearing changes. Causes can include labyrinthitis/vestibular neuritis or benign paroxysmal vertigo, as well as posterior circulation stroke or migraine with brainstem aura.

K. Functional Ataxia (Also Called Pseudoataxia or Conversion Disorder)

In functional ataxia, the patient appears to lurch and stagger when walking, the gait is not wide-based, and falls are rare. The findings on the neurologic examination are often inconsistent and incompatible with neuroanatomic localization, meeting DSM-V criteria for functional symptoms.
**CHRONIC & EPISODIC ATAXIAS**

**Differential Diagnosis**

1. **Inborn Errors of Metabolism**

Inborn errors of metabolism should be strongly considered for both intermittent and chronic ataxia. Metabolic disorders known to cause epidemic or progressive ataxia include amino-acidopathies, urea cycle defects, primary lactic acids, leukodystrophies, lysosomal disorders, peroxisomal disorders, and disorders of glycosylation. Since some of these disorders are treatable, consider sending screening labs such as complete blood count with peripheral smear, compete metabolic panel, thyroid panel, serum organic acids, urine organic acids, lactate, and pyruvate. Depending on these results, additional testing may involve immunoglobulin panel, alpha-fetoprotein, ammonia, vitamin B12, MMA, homocysteine, biotinidase, phytanic acid, homocysteine, vitamin E, copper, ceruloplasmin, lipid panel, acylcarnitine profile, carnitine, or very long chain fatty acids. Ideally, testing is sent when the patient is symptomatic. Brain MRI may also demonstrate characteristic features in some metabolic disorders. For more details, refer to Chapter 36 on Inborn Errors of Metabolism.

2. **Autosomal Dominant Hereditary Ataxias (Chronic and Episodic)**

Most forms of spinocerebellar ataxia (SCA) and episodic ataxia are dominantly inherited, and many are due to channelopathies. Channelopathies are a broad category of disorders that result from altered function of ion channels and membrane excitability in neurons and other cells. Examples include episodic ataxia type 1 (EA1), which is due to a mutation in KCNA1, a potassium channel, and episodic ataxia type 2 (EA2) which is caused by a mutation in CACNA1A, a calcium channel. Interestingly, CACNA1A mutations can also cause spinocerebellar ataxia type 6 (SCA6), as well as hemiplegic migraine and epilepsy. Over 40 dominantly inherited spinocerebellar ataxias have been described, and the various forms often have distinctive features, such as downbeat nystagmus or palatal tremor.

3. **Autosomal Recessive Hereditary Ataxias**

The two most common autosomal recessive hereditary ataxias affecting children are Friedreich ataxia and ataxia-telangiectasia and are discussed below. In addition, rare but treatable autosomal recessive ataxias include ataxia with vitamin E deficiency, cerebrotendinous xanthomatisis, mitochondrial disorders, Refsum disease, and abetalipoproteinemia.

**A. Friedreich Ataxia**

Friedreich ataxia is the most common autosomal recessive ataxia. The classic presentation is a school-aged/adolescent with progressive clumsiness, sensory loss, and weakness that ultimately leads to loss of ambulation by young adulthood. Patients can develop orthopedic deformities, including scoliosis, as well as dysarthria, hypertrophic cardiomyopathy, and diabetes mellitus. Friedreich ataxia is caused by a triplet GAA expansion in the frataxin gene (FXN).

**B. Ataxia-Telangiectasia**

Ataxia-telangiectasia is a multisystem disorder arising from a defect in DNA repair and is the second most common autosomal recessive ataxia. Greater than 99% of individuals with classic ataxia-telangiectasia have mutations in the ATM gene. Patients typically present between 1 and 4 years of age with ataxia, oculomotor apraxia, recurrent infections (due to immunoglobulin deficiencies), and conjunctival telangiectasias. Choreoathetosis and sensorimotor neuropathy are also quite common. Serum alpha-fetoprotein is typically elevated but can be normal early in the course. Patients are at increased risk of malignancy.

**MOVEMENT DISORDERS**

Movement disorders (also called extrapyramidal disorders) are characterized by the presence in the waking state of excessive, unwanted movements: dyskinesias, athetosis, chorea, ballismus, tremors, rigidity, tics, and dystonias. The precise pathologic and anatomic localizations of these disorders are not understood. Motor pathways synapsing in the striatum (putamen and caudate nucleus), globus pallidus, red nucleus, substantia nigra, and the subthalamic nucleus are involved. This system is modulated by pathways originating in the cortex, thalamus, cerebellum, and reticular formation.
1. Chorea and Athetosis

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Chorea is characterized by brief, random involuntary uncoordinated movements of the limbs and face which can flow from one muscle group to the next, resulting in a “dance-like” motion.
- Athetosis involves slow, involuntary writhing or twisting movements.
- Sydenham chorea, a major Jones criteria for rheumatic fever, is a common cause of acute choreoathetoid movements in children, but other etiologies should also be considered.

**Clinical Findings**

Sydenham chorea is a common cause of acute onset of choreoathetoid movements and is a major Jones criteria for rheumatic fever (see Chapter 20 for additional information about rheumatic fever). Hemichorea (involving only one side of the body) occurs in up to 35% of patients. Other symptoms and signs include behavior changes, sleep disturbances, hypotonia, and motor impersistence, such as inability to sustain grip (“milkmaid’s sign”) or tongue protrusion (“tongue darting”). Diagnostic testing should include CBC, ESR, CRP, antistreptolysin O titers, and anti-DNase titer. Strep throat culture should be obtained but is often negative due to the delay between infection and development of chorea. ECG and echocardiography are critical to evaluate for cardiac involvement, which is seen in up to 80% of patients.

**Differential Diagnosis**

Brain MRI should be obtained in all children with chorea to rule out basal ganglia pathology. Though pediatric autoimmune neuropsychiatric disorder associated with Streptococcal infections (PANDAS) is a controversial diagnosis, other paraneoplastic and other autoimmune disorders can certainly cause acquired movement disorders. Additional laboratory testing should be considered to exclude other causes, such as antineuronal antibodies (to evaluate for lupus), antiphospholipid antibodies (to screen for other autoimmune causes), thyroid screening tests, serum calcium for hypocalcemia, HIV, parvovirus B19, and Epstein-Barr virus infection. Benign hereditary chorea (BHC) is an autosomal dominant genetic disorder that can be associated with intellectual disability, hypotonia, congenital hypothyroidism, and chronic lung disease. Tics can mimic chorea. Rare causes, such as drug-induced extrapyramidal syndromes, dyskinetic cerebral palsy, Huntington chorea, hepatolenticular degeneration (Wilson disease), typically cause subacute-chronic symptoms.

**Treatment and Prognosis**

Patients with Sydenham chorea require appropriate antibiotic prophylaxis for rheumatic fever, but no other specific treatment for Sydenham chorea has been developed. Prednisone and, in severe cases, IVIg have been successful. Anticonvulsants, such as sodium valproate or levetiracetam, can reduce chorea symptoms. Emotional lability and depression sometimes require psychologic and pharmacologic treatment. Sydenham chorea is a self-limited disease that may last from a few weeks up to 18 months. Relapse of chorea may occur with nonspecific stress or illness - or with breakthrough streptococcal infections. In follow up studies, valvular heart disease occurred in about one-third of patients, particularly if other rheumatic manifestations had been present as part of the childhood illness. Neuropsychologic disturbances were also present in many patients.

2. Tics/Tourette Syndrome

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Tics are paroxysmal, repetitive, rapid, involuntary movements or vocalizations. Tics “wax and wane” and are variable over time.
- Tourette syndrome is characterized by multiple motor tics and at least one vocal tic with onset before age 21 years and occurring for at least one year.

**Clinical Findings**

Tics are quick, repetitive but irregular, involuntary movements, which are often stereotyped and briefly suppressible. Tics affect up to 20% of school-aged children. Transient tic disorder lasts from 1 month to 1 year. Chronic tic disorder requires more than 1 year of motor or vocal tics. Tourette syndrome is characterized by both motor and vocal tics with no obvious cause, lasting more than 1 year. A premonitory urge (“I had to do it”), transient but effortful suppressibility, and sense of relief after completing the tic are characteristic for tic disorders. Tics generally wax and wane in frequency, and the type of movement evolves over time. Like many movement disorders, tics can be exacerbated by stress or excitement and generally resolve during sleep. Important common comorbidities are attention deficit hyperactivity disorder (ADHD), obsessive-compulsive disorder, academic difficulties, migraine, sleep difficulties, anxiety, and depression.
Motor tics can occur anywhere on the body, but most commonly affect the head, neck, and upper body. Facial tics can include grimaces, twitches, and eye blinking. Complex motor tics are coordinated, sequenced movements that can mimic voluntary motor acts, such as ear/nose scratching or jumping. Vocal tics can manifest as sniffing, grunting, throat clearing, barking, and in complex forms involve the use of words. Coprolalia and echolalia are relatively infrequent. Vocal tics are less common and are highly suggestive of Tourette syndrome. Self-injurious behavior can occur in Tourette syndrome.

Most patients presenting with tics do not require further diagnostic workup. However, a careful history should screen for secondary causes as well as comorbidities and investigate further as indicated.

**Differential Diagnosis**

Tics may be a symptom of other neurologic diseases such as brain injury, autism, Rett syndrome, and numerous genetic neurodevelopmental disorders. Acute brain lesion such as tumor, stroke, or infection will typically be associated with other symptoms. Post-infectious causes such as PANDAS or pediatric acute-onset neuropsychiatric symptoms (PANS) have been long debated, but can be considered if history suggests.

**Treatment and Prognosis**

The cornerstone of treatment is reassurance and education for the patient, family, and school about the nature of tic disorders. Importantly, if the tics are not bothersome to the child and are not causing physical or social impairment, no pharmacologic treatment is necessary. However, screening for and treating common comorbidities, such as ADHD, obsessive-compulsive symptoms, and anxiety, can significantly improve quality of life and sometimes lessen tic severity. Stimulant medications do not need to be avoided due to concern that tics might be exacerbated—recent studies have shown that medications such as methylphenidate improved ADHD symptoms without worsening tics. Habit reversal therapy and Comprehensive Behavioral Intervention for Tics (CBIT) can be effective approaches for tics and various comorbidities. Most pediatric patients will have significant improvement or resolution of tics later in life. Tourette syndrome is considered a life-long disorder and may wax and wane, and in some severe cases may be disabling.

If pharmacologic treatment is warranted, the choice of therapy can be tailored to the child’s needs and comorbidities. Clonidine and guanfacine are considered first-line, especially in a child with comorbid ADHD. Topiramate has a mild side effect profile and may be indicated if the patient has headaches or epilepsy. If tics are refractory to first-line agents, pimozide and fluphenazine are recommended next options, followed by antipsychotics, such as risperidone and aripiprazole. Haloperidol is FDA-approved for Tourette syndrome; however, due to the risk of tardive dyskinesia, it is typically reserved for refractory cases.

### 3. Primary Dystonia and Paroxysmal Dyskinesias

Dystonia is sustained or intermittent involuntary muscle contractions, frequently resulting in twisting movements or abnormal postures. Not all dystonia is due to co-contraction of opposing muscle groups. Secondary causes include cerebral palsy, stroke, tumor, and medication effect. However, primary dystonia can be mistakenly diagnosed as cerebral palsy. Any child with dystonia of unknown cause should have a trial of low-dose L-dopa; a prompt improvement suggests dopa-responsive dystonia (DYT5, also called Segawa disease), a genetic dystonia that is quite sensitive to oral L-dopa. Oppenheim’s dystonia (DYT1) is another genetic cause of dystonia that can manifest in childhood.

Paroxysmal dyskinesias are sudden-onset, short-duration choreoathetosis or dystonia episodes. Most often these episodes are familial or genetic in origin. Episodes may occur spontaneously or be set off by actions (“kinesigenic,” or movement-induced) such as standing up suddenly. Table 25–17 outlines the features of the most common paroxysmal dyskinesias.

### 4. Tremor

Tremor is a rhythmic, involuntary oscillatory movement across a joint axis and is often due to alternating contraction of opposing muscle groups. Resting tremors are most prominent when the involved muscles are completely at rest. In contrast, action tremors become more prominent when

<sup>b</sup>Paroxysmal non-kinesigenic dyskinesia.  
<sup>c</sup>Paroxysmal exercise-induced dyskinesia.
the affected muscles are engaged, for example to maintain a posture (postural tremor) or to move to a target (intention tremor). The most common causes of tremor in the pediatric population are enhanced physiologic tremor, essential tremor, and psychogenic tremor. Numerous medications can exacerbate physiologic tremor, such as asthma medications, antidepressants, stimulants, antipsychotics, and anticonvulsants. Patients with essential tremor often have a family history of tremor, note worsening with caffeine, and have transient improvement with alcohol. Differential diagnosis includes birth asphyxia, Wilson disease, hyperthyroidism, and hypercalcemia; history and laboratory tests rule out these rare possibilities.

CEREBRAL PALSY

The term cerebral palsy is a nonspecific term used to describe a chronic, static impairment of muscle tone, strength, coordination, or movements. The term implies that the condition is nonprogressive and originated from some type of cerebral insult or injury before birth, during delivery, or in the perinatal period. Other neurologic deficits or disorders (eg, blindness, deafness, intellectual disability, or epilepsy) often coexist. Some form of cerebral palsy occurs in about 0.2% of live births. The fundamental course, severity, precise manifestations, and prognosis vary widely.

Clinical Findings

A. Symptoms and Signs

The most common forms of cerebral palsy (75% of cases) involve spasticity of the limbs. A variety of terms denote the limbs affected: monoplegia (one limb); hemiplegia (arm and leg on same side of body, but arm more affected than leg); paraplegia/diplegia (both legs affected with arms unaffected); quadriplegia (all four limbs affected equally). Ataxia is the second most common form of cerebral palsy, accounting for about 15% of cases. The ataxia frequently affects fine coordinated movements of the upper extremities, but may also involve lower extremities and trunk. A dyskinetic movement disorder usually in the form of choreoathetosis or dystonia accounts for 5% of cases and persistent hypotonia without spasticity for 1%.

Depending on the type and severity of the motor deficits, associated neurologic deficits or disorders may occur: epilepsy in 25%, intellectual disability in 50% (that is severe in 25%), disorders of language, speech, vision, hearing, and sensory perception are found in varying degrees and combinations.

The findings on physical examination are variable and are predominantly those of spasticity, hyperreflexia, and, less often ataxia and/or involuntary movements. In patients with hemiplegia, the affected arm and leg may be smaller and shorter than the unaffected limbs. Cataracts, retinopathy, and congenital heart defects may be indicative of congenital infections such as CMV and rubella. It is important to note that, while this is considered a static process, the degree of impairment is not typically visible until the child has at least reached the ages of 3–4 years; children can be said to “grow into” their deficits as they age through infancy and toddlerhood.

B. Laboratory and Imaging Tests

Appropriate studies depend on the history and physical findings. MRI is helpful in understanding the full extent of cerebral injury in about 90% of cases, and occasionally neuroimaging results suggest specific etiologies (eg, periventricular calcifications in congenital CMV, perinatal strokes, or brain malformations). Genetic and metabolic testing should be targeted based on history or MRI findings.

Differential Diagnosis

It should be noted that the diagnosis of cerebral palsy is a descriptor. There must be some underlying etiology that leads to this constellation of symptoms. If identifiable, this is often helpful from a pathologic and prognostic standpoint and should be investigated if an etiology is not clear at diagnosis. No definite etiologic diagnosis is possible in 25% of cases. The incidence is high among infants small for gestational age or with extreme preterm birth. Intrauterine hypoxia is a frequent cause. Other known causes are intrauterine bleeding, infections, toxins, congenital brain malformations, obstetric complications (including birth hypoxia), neonatal infections, kernicterus, neonatal hypoglycemia, metabolic disorders, and a small number of genetic syndromes.
TREATMENT & MANAGEMENT

Treatment and management are directed at assisting the child to attain maximal neurologic functioning with appropriate physical, occupational, and speech therapy. Orthopedic monitoring and intervention and special educational assistance may all contribute to an improved outcome. Treatment of spasticity (with medications for tone or botulinum toxin) and seizures are needed in many children. Constraint-induced movement therapy can help with the affected extremity. Also important is the general support of the parents and family with counseling, educational programs, and support groups.

PROGNOSIS

The prognosis for patients with cerebral palsy depends greatly on the child’s IQ, severity of the motor deficits, etiology of CP, and degree of disability. In severely affected children, aspiration, pneumonia, or other intercurrent infections are the most common causes of death.

In contrast, patients with mild cerebral palsy may improve with age. Some patients experience resolution of their motor deficits by age 7 years. Ambulatory status at 12 years of age is most predictive of adult functional ability. Many children may have normal intellect, normal life spans, and are able to lead productive, satisfying lives.

Clinical Findings

A. Symptoms and Signs

Patients with CNS infections, whether caused by bacteria, viruses, or other microorganisms, present with similar manifestations. These include systemic signs of infection, such as fever, malaise, chills, and organ dysfunction, and specific features suggesting CNS infection including headache, stiff neck, fever or hypothermia, changes in mental status (including hyperirritability evolving into lethargy and coma), seizures, and focal sensory and motor deficits. Meningeal irritation is indicated by the presence of Kernig and Brudzinski signs. In very young infants, signs of meningeal irritation may be absent, and temperature instability and hypothermia are more common than fever. In young infants, a bulging fontanelle and an increased head circumference are common. Papilledema may eventually develop, particularly in older children and adolescents. Cranial nerve palsies may develop acutely or gradually during neurologic infections. No specific clinical sign or symptom is reliable in distinguishing bacterial infections from infections caused by other microbes.

During the initial clinical assessment, conditions that predispose the patient to infection of the CNS should be sought. Infections involving the sinuses or other structures in the head and neck region can result in direct extension of infection into the intracranial compartment. Open head injuries, recent neurosurgical procedures, immunodeficiency, and the presence of a mechanical shunt may predispose to intracranial infection.

B. Laboratory Findings

When CNS infections are suspected, blood should be obtained for a complete blood count, chemistry panel, and culture. Most important, however, is obtaining CSF. In the absence of focal neurologic deficits or signs of brainstem herniation, CSF should be obtained immediately from any patient in whom serious CNS infection is suspected. When papilledema or focal motor signs are present, a lumbar puncture may be delayed until either at CT scan or MRI of the brain has been done to exclude space-occupying lesions. Antimicrobial treatment must be started even if lumbar puncture is delayed. It is generally safe to obtain spinal fluid from infants with nonfocal neurologic examination even if the fontanelle is bulging. Spinal fluid should be examined for the presence of red and white blood cells, protein concentration, glucose concentration, bacteria, and other microorganisms; a sample should be cultured. In addition, serologic, immunologic, and nucleic acid detection (PCR) tests may be performed on the spinal fluid. Many labs have multiplex PCR panels that allow for rapid testing of many pathogens. Identification of a pathogen may allow for customized treatment. Spinal fluid that contains a high
proportion of polymorphonuclear leukocytes, a high protein concentration, and a low glucose concentration strongly suggests bacterial infection (see Chapter 42). CSF containing predominantly lymphocytes, a high protein concentration, and a low glucose concentration suggests infection with mycobacteria, fungi, uncommon bacteria, and some viruses such as lymphocytic choriomeningitis virus, herpes simplex virus, mumps virus, and arboviruses (see Chapters 40 and 43). CSF that contains a high proportion of lymphocytes, normal or only slightly elevated protein concentration, and a normal glucose concentration is suggestive of viral infections and CNS inflammatory disorders, although partially treated bacterial meningitis and parameningeal infections may also result in this CSF profile. Typical CSF findings in a variety of infectious and inflammatory disorders are shown in Table 25–2.

Herpes simplex virus infections can be confirmed using PCR to detect for herpes DNA in spinal fluid. This test has 95% sensitivity and 99% specificity. If clinical suspicion is high with a negative result, continue to treat and repeat PCR in 2–3 days. Rarely, brain biopsy may be needed to detect the rare PCR-negative case of herpes simplex, various parasitic infections, or in a suspected parainfectious or postinfectious cause with ambiguous spinal fluid findings (eg, vasculitis).

C. Imaging

Neuroimaging with CT and MRI scans may be helpful in demonstrating the presence of brain abscess, meningeal inflammation, or secondary problems such as venous and arterial infarctions, hemorrhages, and subdural effusions when these are suspected. In addition, these procedures may identify sinus or other focal infections in the head or neck region that are related to the CNS infection.

Although often nonspecific, EEGs may be helpful in the assessment of patients who have had seizures at the time of presentation. In some instances, such as herpes simplex virus or focal enterovirus infection, periodic lateralized epileptiform discharges (PLEDs) may be seen early in the course and may be one of the earliest study abnormalities to suggest the diagnosis. EEGs may also show focal slowing over regions of infarcts or (rare) abscesses.

Bacterial meningitis

Bacterial infections of the CNS may present acutely (symptoms evolving rapidly over 1–24 hours), subacutely (symptoms evolving over 1–7 days), or chronically (symptoms evolving over more than 1 week). Diffuse bacterial infections involve the leptomeninges, superficial cortical structures, and blood vessels. Although the term meningitis is used to describe these infections, it should not be forgotten that the brain parenchyma is also inflamed and that blood vessel walls may be infiltrated by inflammatory cells that result in endothelial cell injury, vessel stenosis, and secondary ischemia and infarction. Overall clinical characteristics of bacterial meningitis (and viral meningoencephalitis) are outlined in Table 25–18.

Acute bacterial meningitis (and viral meningoencephalitis) are outlined in Table 25–18. While awaiting the results of diagnostic tests, the physician should start broad-spectrum antibiotic coverage. The appropriate antimicrobial varies with age to match the likely pathogens encountered at a given age. After specific organisms are identified, antibiotic therapy can be tailored based on antibiotic sensitivity patterns.

Suspected bacterial meningitis in neonates is treated initially with ampicillin and cefotaxime. Ampicillin and Gentamicin may be used in the case of fever in a neonate.

**Treatment**

A. Specific Measures

(See also Chapters 39, 40, and the section on bacterial infections in Chapter 42.)

While awaiting the results of diagnostic tests, the physician should start broad-spectrum antibiotic coverage. The appropriate antimicrobial varies with age to match the likely pathogens encountered at a given age. After specific organisms are identified, antibiotic therapy can be tailored based on antibiotic sensitivity patterns.

Suspected bacterial meningitis in neonates is treated initially with ampicillin and cefotaxime. Ampicillin and Gentamicin may be used in the case of fever in a neonate.
Cefotaxime should be used if a gram-negative organism is suspected. Ampicillin is used to treat *Listeria* and entero- cocci infections, which rarely affect immune-competent older children. Thus, children older than 3 months are given ceftriaxone or cefotaxime plus vancomycin to empirically treat for the most common bacterial pathogens, penicillin-resistant *S pneumoniae* and *N meningitides*. Rifampin and dexamethasone use should be considered on a case by case basis. Therapy may be narrowed when organism sensitivity is determined. Duration of therapy is 7 days for meningococcal infections, 10 days for *Haemophilus influenzae* or pneumococcal infection, and 14–21 days for other organisms. Slow clinical response or the occurrence of complications may require prolonged therapy.

Meningitis in a child with a ventriculoperitoneal shunt is most commonly caused by coagulase-negative staphylococci, many of which are methicillin-resistant. In many of these patients who are not seriously ill, therapy should be postponed while awaiting the appropriate shunt fluid for Gram stain and culture. Seriously ill patients should initially be given vancomycin and a third-generation cephalosporin, because *Staph aureus* and gram-negative rods are also common causes of serious infection.

### B. General and Supportive Measures

Children with bacterial meningitis are often systemically ill. The following complications should be looked for and treated aggressively: hypovolemia, hypoglycemia, hyponatremia, acidosis, septic shock, increased intracranial pressure, seizures, disseminated intravascular coagulation, and metastatic infection (eg, pericarditis, arthritis, or pneumonitis). Children should initially be monitored closely (cardiorespiratory monitor, strict fluid balance and frequent urine specific gravity assessment, daily weights, and neurologic assessment every few hours), not fed until neurologically stable, isolated until the organism is known, rehydrated with isotonic solutions, and then given intravenous fluids containing dextrose and sodium at no more than maintenance rate (assuming no unusual losses occur).

#### Complications

**Abnormalities of water and electrolyte balance** result from either excessive or insufficient production of antidiuretic hormone and require careful monitoring and appropriate adjustments in fluid administration. Monitoring serum sodium every 8–12 hours during the first 1–2 days, and urine sodium if the inappropriate secretion of antidiuretic hormone is suspected, will usually uncover significant problems.

**Seizures** occur in 20%–30% of children with bacterial meningitis. Most seizures occur early during infection. Seizures tend to be most common in neonates and less common in older children. Persistent focal seizures or focal seizures associated with focal neurologic deficits strongly suggest subdural effusion, abscess, or vascular lesions such as arterial infarct, cortical venous infarcts, or dural sinus thrombosis. Because generalized seizures in a metabolically compromised child may have severe sequelae, early recognition and therapy are critical.

**Subdural effusions** occur in up to a third of young children with *S pneumoniae* meningitis. Subdural effusions are often seen on CT scans of the head during the course of meningitis. They do not require treatment unless they are producing increased intracranial pressure or progressive mass effect. Although subdural effusions may be detected in children who have persistent fever, such effusions do not usually have to be sampled or drained if the infecting organism is *H influenzae*, meningococcus, or pneumococcus. These are usually sterilized with the standard treatment, and slowly waning fever during an otherwise uncomplicated recovery may be followed clinically. Under any other circumstance, however, aspiration of the fluid for documentation of sterilization or for relief of pressure should be considered. Prognosis is not worsened by subdural effusions.

**Cerebral edema** results in increased intracranial pressure, requiring treatment with dexamethasone, osmotic agents, diuretics, or hyperventilation; intracranial pressure monitoring may be needed.

Long-term sequelae of meningitis result from direct inflammatory destruction of brain cells, vascular injuries, or secondary gliosis. Focal motor and sensory deficits, visual impairment, hearing loss, seizures, hydrocephalus, and a variety of cranial nerve deficits can result. Sensorineural hearing loss in *H influenzae* meningitis occurs in approximately 5%–10% of patients during long-term follow-up. Early addition of dexamethasone to the antibiotic regimen may modestly decrease the risk of hearing loss in some children with *bacterial meningitis* (see Chapter 42).

In addition to the disorders mentioned, some patients with meningitis develop mild to severe cognitive impairment and severe behavioral disorders that limit their function at school and later performance in life.

### BRAIN ABSCESS

#### Clinical Findings

Patients with brain abscess often appear to have systemic illness similar to patients with bacterial meningitis, but in addition they may show signs of focal neurologic deficits, papilledema, and other evidence of increased intracranial pressure or a mass lesion. Symptoms may be present for a week or more; children with bacterial meningitis usually present within a few days. Conditions predisposing to development of brain abscess include penetrating head trauma; chronic infection of the middle ear, mastoid, or sinuses (especially the frontal sinus); chronic dental or pulmonary infection; cardiovascular lesions allowing right-to-left shunting of blood (including arteriovenous malformations); and endocarditis.
When brain abscess is strongly suspected, a neuroimaging procedure such as CT or MRI scan with contrast enhancement should be done prior to lumbar puncture. If a brain abscess is identified, lumbar puncture may be dangerous and rarely alters the choice of antibiotic or clinical management since the CSF abnormalities usually reflect only parameningeal inflammation or are normal. With spread from contiguous septic foci, streptococci and anaerobic bacteria are most common. Staphylococci most often enter from trauma or spread from distant infections. Enteric organisms may form an abscess from chronic otitis. Cultures from many brain abscesses are negative, but Gram stain may be informative.

The diagnosis of brain abscess is based primarily on a strong clinical suspicion and confirmed by a neuroimaging procedure. Strongly positive inflammatory markers (erythrocyte sedimentation rate, C-reactive protein) may be supportive as normal results would be unlikely in patients with brain abscess. EEG changes are nonspecific but frequently demonstrate focal slowing in the region of brain abscess.

**Differential Diagnosis**

Differential diagnosis of brain abscess includes any condition that produces focal neurologic deficits and increased intracranial pressure, such as neoplasms, subdural effusions, cerebral infarctions, and other CNS infections.

**Treatment**

When a primary source or contiguous focus is suspected Ceftriaxone plus metronidazole is recommended. Penicillin G is an alternative to a cephalosporin and is effective against most mouth flora. In posttraumatic and postsurgical cases, nafcillin or oxacillin plus a third-generation cephalosporin (cefotaxime or ceftriaxone) is recommended. Vancomycin should be considered as a substitute for nafcillin or oxacillin when methicillin-resistant *Staphylococcus aureus* is suspected. Treatment may include neurologic consultation and anticonvulsant therapy when necessary. In their early stages, brain abscesses are areas of focal cerebritis and can be treated with antibiotic therapies alone. Encapsulated abscesses require surgical drainage.

**Prognosis**

The surgical mortality rate in the treatment of brain abscess is lower than 5%. Untreated cerebral abscesses lead to irreversible tissue destruction and may rupture into the ventricle, producing catastrophic deterioration in neurologic function and death. Because brain abscesses are often associated with systemic illness, the death rate is frequently high in these patients. Other poor prognostic indicators include rapid progression of disease and alteration of consciousness at the time of presentation.

**VIRAL INFECTIONS**

Viral infections of the CNS can involve meninges (meningitis) (see Chapter 40) or parenchyma (encephalitis). All patients, however, have some degree of involvement of both the meninges and cerebral parenchyma (meningoencephalitis). Many viral infections are generalized and diffuse, but some viruses, notably herpes simplex and some enteroviruses, characteristically cause prominent focal disease. Focal cerebral involvement is clear on neuroimaging procedures. Some viruses have an affinity for specific CNS cell populations. Poliovirus and other enteroviruses (A71 and D68) can selectively infect anterior horn cells and some intracranial motor neurons.

Although most viral infections of the nervous system have an acute or subacute course in childhood, chronic infections can occur. Subacute sclerosing panencephalitis, for example, represents a chronic indolent infection caused by altered measles virus and is characterized clinically by progressive neurodegeneration and seizures.

Treatment of CNS viral infections is usually limited to symptomatic and supportive measures, except for herpes simplex virus, and some cases of varicella-zoster virus infections where acyclovir is used (see HSV section within the Viral and Rickettsial diseases chapter). West Nile virus is an arthropod-borne flavivirus. It is found in mosquitoes, thus the highest incidence of West Nile virus infections occurs from July to October. The infection is now endemic in United States. This disease is often asymptomatic or mild in pediatric patients; paralysis and death occur mostly in the elderly.

**ENCEPHALOPATHY OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION**

Neurologic syndromes associated directly with HIV infection include subacute encephalitis, meningitis, myelopathy, polyneuropathy, and myositis. In addition, opportunistic infections of the CNS occur in patients with HIV-induced immunosuppression. *Pneumocystis*, *Toxoplasma*, and CMV infections are particularly common. Progressive multifocal leukoencephalopathy caused by a secondary papillomavirus infection, and herpes simplex and varicella-zoster infections also occur frequently in patients with untreated HIV infection. Various fungal (especially cryptococcal), mycobacterial, and bacterial infections occur.

Neurologic abnormalities in these patients can also be the result of noninfectious neoplastic disorders. Primary CNS lymphoma and metastatic lymphoma to the nervous system are the most frequent neoplasms of the nervous system in these patients. See Chapters 33, 39, and 41 for diagnosis and management of HIV infection.
OTHER INFECTIONS

A wide variety of other microorganisms, including Toxoplasma, mycobacteria, spirochetes, rickettsiae, amoebae, and mycoplasma, can cause CNS infections. CNS involvement in these infections is usually secondary to systemic infection or other predisposing factors. Appropriate cultures and serologic testing are required to diagnose these infections. Parenteral antimicrobial treatment for these infections is discussed in Chapter 39.

NONINFECTIOUS INFLAMMATORY DISORDERS OF THE CENTRAL NERVOUS SYSTEM

The differential diagnosis of bacterial, viral, and other microbial infections of the CNS includes disorders that cause inflammation but for which no specific causal organism has been identified. Sarcoidosis, Behçet disease, systemic lupus erythematosus, and other collagen-vascular disorders are examples. In these disorders, CNS inflammation usually occurs in association with characteristic systemic manifestations that facilitate diagnosis. Some CNS inflammatory disorders lead to demyelination syndromes described in Table 25–19. Management of CNS involvement in these disorders is the same as the treatment of the systemic illness.

A. Acute Demyelinating Encephalomyelitis

Inflammatory reactions within the nervous system may occur during the convalescent stage of systemic viral infections.

Table 25–19. Prominent features of CNS inflammatory demyelination syndromes.

</tbody>
</table>

Parainfectious or postinfectious inflammation of the CNS results in several well-recognized disorders: acute disseminated encephalomyelitis (ADEM; 25% of encephalitis), transverse myelitis, optic neuritis, polynuerritis, and GBS.

Clinical Findings

a. Imaging

MRI findings in ADEM are distinctive: demyelinating lesions, seen on T2 and FLAIR images, are key to the diagnosis. White matter lesions can mimic findings in MS, but more likely are large and ill-defined. White matter lesions may also involve gray matter such as cortex, basal ganglia, and thalamus. Radiologic changes are usually florid when the patient presents but occasionally emerge days later. In cases of uncertain diagnosis, serial or repeat scans may be necessary. Unlike the demyelinating lesions of MS, ADEM lesions usually resolve within months of presentation.

b. Laboratory Findings

Lumbar puncture findings may be normal or mildly abnormal, with mild pleocytosis and elevation of the CSF protein in 25%–50% of cases. Oligoclonal bands are not typically seen in ADEM, but rather are commonly found in chronic, relapsing conditions like MS. Oligoclonal bands may also be seen in chronic infections and viral syndromes.

Treatment

Corticosteroids are the primary treatment for ADEM. Current practice is to administer high-dose, followed by oral prednisone taper over 4–6 weeks. Most pediatric groups initially use intravenous methylprednisolone (10–30 mg/kg/days up to a maximum dose of 1 g/days). In refractory patients, IVIg or plasmapheresis may be effective.

Prognosis

Rarely, ADEM relapses within 3 months of onset. Recurrence more than 3 months after the initial treatment should raise suspicion of MS, neuromyelitis optica spectrum disorder (especially in cases of optic nerve or spinal cord involvement) or alternative cause. Congenital viral infections can also affect the CNS. CMV, herpes simplex virus, varicella, and (rare now, because of immunization) rubella virus are the most notable causes of viral brain injury in utero.

B. Paraneoplastic Syndromes

Paraneoplastic syndromes are increasingly recognized. These immune-mediated disorders are clinically heterogeneous with neurologic effects that can be both central and peripheral. The disorders are identified by autoantibodies...
Multiple Sclerosis

Five to ten percent of patients with MS are diagnosed before the age of 18 years. Many patients diagnosed in adulthood report having symptoms attributable to MS prior to age of 18 years. The epidemiology, pathophysiology, diagnosis and treatment of pediatric MS are areas of study. Several exciting discoveries have highlighted the importance of genetic and environmental risk factors for pediatric MS. Notable examples include HLA subtypes, viral exposures, smoking exposure, childhood obesity, vitamin D deficiency, and others. Importantly, diagnostic criteria, including clinical, MRI, and laboratory studies are different among prepubertal patients when compared to postpubertal patients.

Clinical Findings

The diagnosis of MS in a child remains challenging as the presenting clinical signs and symptoms may be similar or identical to acute disseminated encephalomyelitis, despite the same pathophysiology. An earlier age at disease presentation may be associated with specific features such as encephalopathy, seizures, and brainstem and cerebellar symptoms.

A diagnosis of MS requires demyelination separated in time and space. However, a diagnosis of pediatric MS may be made after one episode of demyelination if the MRI scan meets criteria for dissemination in time and space as described in the McDonald 2010 diagnostic criteria. If these criteria are not met, the child is diagnosed with clinically isolated syndrome, for example, optic neuritis; transverse myelitis; or brainstem, cerebellar, or hemispheric dysfunction. If the patient develops subsequent clinical or radiographic changes that meet criteria for MS, he/she may be diagnosed at that time. Atypical clinical features of pediatric MS include fever and involvement of the peripheral nervous system or other organ systems, elevated erythrocyte sedimentation rate or marked CSF pleocytosis. Encephalopathy is more commonly associated with ADEM. However, in young children, MS exacerbations may present with encephalopathy, making differentiation of the two disorders difficult.

The initial brain MRI scan of younger patients shows more frequent involvement of the posterior fossa and higher numbers of ovoid, ill-defined T2-bright foci that often partially resolve on the follow-up scan. At present, there are several sophisticated MRI criteria to separate pediatric MS diagnosis from alternative diagnoses (eg, ADEM).

Finally, the spinal fluid in younger patients may fail to reveal oligoclonal bands or elevated IgG index at disease onset. There is no FDA-approved therapy for MS in children, but several studies are underway. Current practice is to use disease-modifying therapies that are approved for adults. Retrospective data have shown them to be effective in children.

Differential Diagnosis

Differential diagnosis includes ADEM, idiopathic transverse myelitis, optic neuritis, rheumatologic disorders such as systemic lupus erythematosus, Behcet and Sjögren syndrome and neuromyelitis optica. Many other infections, metabolic disorders, and degenerative diseases can mimic MS. A newly recognized syndrome characterized by anti-myelin oligodendrocyte glycoprotein (MOG) antibodies, Anti-MOG Syndrome, may account for cases previously thought to be atypical pediatric MS or ADEM.

Treatment

Acute treatment of relapses includes high dose intravenous methylprednisolone and occasionally plasmapheresis. The use of disease-modifying therapies in children is based on adult randomized controlled trials and retrospective experience. Pediatric clinical trials are underway. Immuno-modulatory treatment to prevent relapses in children include injections, oral medications and infusions. Injectable medications include interferon beta-1a, interferon beta-1b, glatiramer acetate, and daclizumab. Oral medications include fingolimod, teriflunomide, and dimethyl fumarate. Intravenous infused drugs include natalizumab, rituximab, ocrelizumab, and alemtuzumab. Cyclophosphamide may be used in refractory patients.

SYNDROMES PRESENTING AS ACUTE FLACCID WEAKNESS

Pathogenesis
Flaccid paralysis in a child can occur as a result of a lesion anywhere along the neuroaxis. The key to diagnosis is localizing the lesion. Associated changes in reflexes, sensory changes, abnormal reflexes such as a positive Babinski’s sign, and bowel and bladder changes can help in localizing the lesion. Mass lesions, infectious or postinfectious causes, toxins (eg, from a tick or due to botulism), and metabolic causes, are only a few of the etiologies that can cause acute weakness. A review of some of the more common causes of acute flaccid weakness and their associated findings are listed in Table 25–20.

Clinical Findings

A. Symptoms and Signs
Features assisting diagnosis are age, a history of preceding illness, rapidity of progression, cranial nerve findings, bowel and bladder changes, and sensory findings (see Table 25–20). The finding of increased reflexes and upgoing toes suggests a CNS lesion. Fatigability when drinking from a bottle and constipation may be seen in infants with botulism. In GBS (also known as acute inflammatory demyelinating polyneuropathy [AIDP]), patients may initially present with an ascending paresthesia and loss of reflexes before they develop overt weakness. Patients with the Miller Fisher variant of GBS may present with a classic constellation of symptoms including ophthalmoplegia, ataxia, and loss of reflexes. Back pain is suggestive of a spinal cord lesion, such as in transverse myelitis or a spinal cord mass.

B. Laboratory Findings
When a spinal cord or brain lesion is suspected, MRI imaging may be helpful, and in fact is essential if a mass lesion is suspected. Once a mass lesion is excluded by imaging, CSF studies, including opening pressure, can be obtained. Viral cultures (CSF, throat, and stool) and titers aid in diagnosing poliomyelitis. A high sedimentation rate may suggest tumor, abscess, or autoimmune disorder.

EMG and nerve conduction studies (NCSs) can be helpful in diagnosing GBS. NCSs are particularly helpful after the first week when delayed or absent H or F reflexes are seen as the first changes. Later, motor NCSs show prolonged distal latency, conduction block or temporal dispersion, with these changes seen in 50% of patients by 2 weeks and 85% by 3 weeks. EMG findings of fibrillation potentials and increased compound muscle action potential amplitudes with high-frequency stimulation are suggestive of botulism. Rarely, elevation of muscle enzymes or even myoglobinuria may aid in diagnosis of acute myopathic weakness.

Differential Diagnosis
Atypical presentations of viral infections such as with influenza A, West Nile virus, and enterovirus should be considered when a patient presents with symptoms of poliomyelitis. Ascending paresthesias and absent reflexes are often early signs of GBS. The weakness of the extremities, respiratory muscles and bulbar muscles can be followed rapidly thereafter. In previously healthy infants who present with acute weakness, botulism should be considered, particularly in endemic areas or with a history of ingesting honey or canned foods. Tick paralysis can be rapidly corrected with removal of the tick, but requires an index of suspicion and a careful search for the offending insect. Patients with transverse myelitis may present with acute weakness and absent reflexes, but in the ensuing weeks will develop hyperreflexia and increased tone in the regions below the area of the lesion.

Complications
A. Respiratory Weakness and Failure
Early careful attention to ventilation is essential, especially in those patients with bulbar weakness and early signs of respiratory failure. Administration of oxygen, intubation, mechanical respiratory assistance, and careful suctioning of secretions may be required. Increasing anxiety and a rise in diastolic and systolic blood pressures are early signs of hypoxia. Cyanosis is a late sign. Deterioration of spirometry

<tr>
<td>EMG/NCS</td>
<td>EMG shows denervation after 10–21 days. No sensory NCS abnormalities</td>
<td>NCSs may be normal early (within 1st week). Earliest changes: slowed to absent F or H reflexes. Demyelinating changes are typically seen 7–10 days after onset of symptoms.</td>
<td>EMG distinctive: BSAP (brief small abundant potentials). High-frequency stimulation may increase in CMAP amplitude but is painful to perform in awake infant.</td>
<td>Nerve conduction velocity slowed; returns rapidly to normal after removal of tick.</td>
</tr>
<tr>
<td>Course and prognosis</td>
<td>Paralysis usually maximal 3–5 days after onset. Transient bladder paralysis may occur. Outlook varies with extent and severity of involvement.</td>
<td>Course progressive over a few days to about 2 wk.</td>
<td>Infancy: supportive.</td>
<td>Total removal of tick is followed by rapid improvement and recovery. Otherwise, mortality rate due to respiratory paralysis is very high.</td>
</tr>
</tbody>
</table>

**Note:** Mortality greatest from respiratory failure and superinfection.

**Note:** Morbidity greatest from respiratory failure (10%), autonomic crises (eg, widely variable blood pressure, arrhythmia), and superinfection. Majority recover completely. Plasmapheresis and IVIg can shorten the hospitalization. Relapses occasionally occur.

Botulism immune globulin intravenous (BIGIV). Respiratory support, gavage feeding. Avoid aminoglycosides. Prognosis: excellent. Fatality 3%.

AIDP, acute inflammatory demyelinating neuropathy; CMAP, compound muscle action potentials; CMV, cytomegalovirus; CSF, cerebrospinal fluid; EBV, Ebstein–Barr virus; EMG, electromyogram; EV-71, enterovirus 71; GI, gastrointestinal; IVIg, intravenous immunoglobulin; MRI, magnetic resonance imaging; NCS, nerve conduction studies; PMN, polymorphonuclear neutrophil; SIDS, sudden infant death syndrome.

*AMAN is acute motor axonal neuropathy (uncommon variant in the United States).
testing: forced expiratory volume in 1 second and total vital capacity, may indicate the need for controlled intubation and respiratory support. At the bedside, measurement of negative inspiratory force (NIF) is recommended at frequent intervals in the acute course as this may be more sensitive to early respiratory failure than blood gases.

B. Infections

Pneumonia is common, especially in patients with respiratory weakness. Antibiotic therapy is best guided by results of cultures. Bladder infections occur when an indwelling catheter is required because of bladder paralysis. Recovery from myelitis may be delayed by urinary tract infection.

C. Autonomic Crisis

This may be a cause of death in GBS. Strict attention to vital signs to detect and treat hypotension or hypertension and cardiac arrhythmias in an intensive care setting is advisable, at least early in the course and in severely ill patients.

Treatment

Ticks causing paralysis must be removed. Botulism immune globulin administration shortens the hospitalization course in infant botulism, as can treatment with IV Ig or plasmapheresis in GBS. Steroids, IV Ig, and/or plasmapheresis have been used in transverse myelitis. Comorbid associated disorders (eg, endocrine, neoplastic, or toxic) should be treated by appropriate means. Supportive treatment is the essence for all of the diagnoses, including pulmonary toilet, adequate fluids and nutrition, bladder and bowel care, prevention of decubitus ulcers, and in many cases, psychiatric support.

DISORDERS OF CHILDHOOD AFFECTING MUSCLES

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Usually painless, symmetric proximal more than distal muscle weakness (positive Gowers sign, excessive lordosis with walking, waddling gait).
- Preserved deep tendon reflexes compared with muscle weakness.
- Normal to elevated serum creatine kinase (CK) levels.
- Generally normal NCSs; myopathic findings on EMG.

Clinical Findings

A. Laboratory Findings and Special Tests

1. Serum enzymes—Serum creatine kinase (CK) levels reflect muscle damage or “leaks” from muscle into plasma. Generally, CK levels are normal to mildly elevated in myopathies, and markedly elevated in muscular dystrophies up to 50–100 times, as in Duchenne muscular dystrophy. Medications and activity level may affect CK levels, for instance after an EMG or muscle biopsy procedure. Corticosteroids may decrease levels despite very active muscle disease, for example, as in polymyositis.

2. Electrophysiologic studies—Nerve conduction study (NCS) and needle EMG are often helpful in differentiating myopathic from neurogenic processes. Generally, NCSs are normal in muscle disorders. In demyelinating polyneuropathies, NCSs may show slowing of conduction velocities or conduction block. EMG involves inserting a needle electrode into muscle to record muscle electrical potentials. The examination includes assessment of abnormal spontaneous activity (eg, fibrillation and fasciculation potentials, and myotonic discharges) and motor unit action potentials (MUAPs). In the myopathies, MUAPs during contraction characteristically are of short duration, polyphasic, and increased in number for the strength of the contraction (increased interference pattern). In neuropathic processes, MUAPs are polyphasic, are of large amplitude, and show decreased recruitment.
3. Muscle biopsy—A muscle biopsy can be helpful in the diagnosis of a muscle disorder, if properly executed. It is important to consider the timing of the biopsy and the biopsied muscle should be chosen based upon the degree of weakness (ie, weaker muscles will show more pathology than strong muscles). Imaging with MRI or ultrasound may guide the choice of an appropriate site. Biopsies performed in the newborn period may be of limited utility as pathologic changes may not be evident in immature muscle. Care should be taken to avoid sites of prior needle EMG examinations or injections as this may cause spurious areas of focal inflammation pathologically. Findings common to the muscular dystrophies include variation in the size and shape of muscle fibers, increase in connective tissue, interstitial infiltration of fatty tissue, areas of degeneration and regeneration, and focal areas of inflammatory changes. Myopathies typically do not have the vigorous cycles of degeneration/regeneration and inflammation seen in dystrophies. Immunostaining for proteins of the sarcolemal membrane, surrounding collagen matrix, and intracellular components of the myofiber is a valuable tool.

4. Genetic testing and carrier detection—Mutation analysis for Duchenne and Becker muscular dystrophy is considered the initial step in diagnosis, though it should be noted that readily available commercial testing is not exhaustive, and an initial negative result does not exclude the diagnosis. Full characterization of the mutation is recommended, as treatments targeting specific mutations are emerging. Carrier testing should be offered to all mothers, not only for genetic counseling purposes but also because carriers are at increased risk for developing cardiomyopathy.

Genetic testing for other myopathies and muscular dystrophies should be guided by the clinical findings, serum CK levels, and muscle biopsy results. Commercially available tests are available for many of these disorders (Table 25–21).

Genetic counseling is particularly important for families of patients with spinal muscular atrophy. Testing for the survival motor neuron (SMN) 1 gene deletion has a sensitivity of 95% and a specificity of 100%. Carrier testing, along with genetic counseling, also should be offered, as the carrier rate is as high as 1 in 40 to 1 in 60, depending upon ethnicity.

Complications

Though skeletal muscle weakness may be profound in muscle disorders, the greatest morbidity and mortality arises from cardiorespiratory complications. Advances in supportive care, especially in critical care management of these patients, have had a tremendous impact in the care of these patients. Noninvasive ventilation, better management of secretions, and generation of effective cough are a few examples. Other complications include delayed gastrointestinal motility which can lead to debilitating constipation or pseudo-obstruction. Contractures are a particularly frustrating complication which can limit mobility of these patients, cause pain, and affect quality of life. Some DMD patients may have a nonprogressive mental retardation with IQ scores one standard deviation below normal means.

Treatment

Treatment for patients with muscle disorders is predominantly supportive, and medications altering disease progression are, at this time, limited. A few examples of treatable conditions include Duchenne muscular dystrophy/Becker muscular dystrophy and Pompe’s disease.

Patients with Duchenne muscular dystrophy (DMD)/Becker muscular dystrophy (BMD) should be offered treatment with corticosteroids (prednisone/prednisolone or deflazacort) which have been shown to extend the period of independent ambulation by approximately 2.5 years, and to preserve respiratory strength and cardiac function into the second decade. Instituting steroid treatment between 4 and 8 years, when motor function plateaus or is in decline, appears to have the greatest impact on muscle strength and cardio-respiratory function, according to recent practice parameter guidelines. Additional promising treatments targeting specific mutations have been developed over the last decade and are currently in clinical trials, including exon-skipping and read-through strategies that target specific mutations.

In the past, the prognosis for infantile Pompe disease was uniformly grim, with death by age 1 year, but ERT with recombinant alglucosidase alfa has changed the outlook for many of these patients. Treatment with ERT in these patients show overall benefit and increased survival, though in the long-term patients may have residual or progressive weakness.

Until curative treatments for muscle diseases are available, the emphasis on management ought to be on slowing the progressive deterioration in muscle strength and cardio-respiratory function, and to improve quality of life.

</table>

**Metabolic myopathies**

- **Pompe disease**
  - Autosomal recessive; 17q23.
  - Severe hypotonia, hepatomegaly, cardiomyopathy, hyperventilation. Proximal muscle weakness.
  - Proximal more than distal muscles, bulbar and respiratory muscles. Recurrent respiratory infections; nocturnal hypoventilation.
  - Cytoplasmic lysosomal vacuoles stain positive with acid phosphatase.
  - High CK in infants (< 10 × normal). Mildly high CK in teens.
  - Enzyme replacement therapy with alglucosidase alfa (Myozyme). Respiratory and nutritional support. Monitor cardiomyopathy. As above.
  - Significant but variable with treatment, with improved survival, cardiorespiratory status and motor skills. Variable, some become nonambulatory and most require ventilatory support.

*(Continued)*
Hyperkalemic periodic paralysis

Autosomal dominant 17q35.

Childhood, usually by 1st decade.

Episodic flaccid weakness, precipitated by rest after exercise, stress, fasting or cold.

Proximal and symmetric muscles, distal muscles may be involved if exercised.

Normal, may be 0 with episode

Hyperkalemic periodic paralysis.

CK normal to 300 IU/L; attacks associated with high serum K+; NCS show increased CMAP amplitude after 5 min exercise.

Many attacks are brief and do not need treatment; treat acute attack with carbohydrates; if needed, chronic treatment with acetazolamide.

Attacks may be more frequent with increasing age.

Congenital muscular dystrophies (CMD)

CMD without CNS involvement: includes laminin α/c mutations, collagen VI myopathies

Autosomal recessive, autosomal dominant.

Birth to 1st mo.

Hypotonia, generalized weakness. Contractures proximally and lax hypermobility distally.

Generalized and respiratory muscle weakness.

0 to +

Laminin α2 deficiency: absent/reduced laminin α2 staining. Collagen VI myopathies: reduced/absent COLVI.

CK normal to 10 × normal. Laminin α2 deficiency: mild neuropathy. Skin changes in collagen VI myopathies: follicular hyperkeratosis.

Most never walk or lose ability to walk early. Respiratory support required early.

Variable: death by 1st–2nd decade secondary to respiratory failure in more severely affected patients

CMD with CNS involvement: dystroglycanopathies including Fukayama (FCMD), Walker-Warburg (WW), Muscle-eye-brain (MEB)

Recessive; 14 genes identified associated with abnormalities of glycosylation of α-dystroglycan.

Birth to 9 mo.

Severe weakness; profound motor delay; severe intellectual disability. MEB with severe congenital myopia, retinal hypoplasia.

Severe generalized weakness.

Variable

Variability in fiber size, internalized nuclei, decreased immunostaining of α-dystroglycan.

CK 400–4000 IU/L, myopathic EMG, small evoked response on electroretinogram, MRI shows white matter changes, migrational abnormalities, lissencephaly, cerebellar hypoplasia.

No curative treatment. Respiratory and nutritional support. Treatment of seizures.

Variable, but generally poor with death by 2nd decade secondary to respiratory failure.
### Myotonic disorders

<table>

(Continued)
Spinal muscular atrophy

**SMA type 1**
- Autosomal recessive, 5q.
- 1st 6 mo of life.
- Hypotonia, “floppy” infant, with alert look, fasciculations may be noted of tongue.
- Severe progressive, symmetric proximal and respiratory muscle weakness; face spared.
- Large areas of grouped muscle fiber atrophy, most larger fibers are type I.
- EMG shows fibrillation and fasciculation potentials, large amplitude motor unit potentials. Normal to mildly elevated CK.
- No curative treatments. Respiratory and nutritional support. Improved gross motor control with neusinersin (Spinraza). Clinical trials underway with sodium phenylbutyrate, valproic acid, and riluzole.
- No independent sitting or standing. Life expectancy < 2 y without respiratory or nutritional support. Likely improved with introduction of neusinersin in 2017.

**SMA type 2**
- 1st 18 mo.
- Motor delays.
- Progressive symmetric proximal muscles, mild to moderate respiratory weakness, limited cough and secretion control.
- EMG also shows fibrillation potentials and large amplitude motor unit potentials, but fasciculations not as common as in SMA type 1; tremor of fingers.
- No curative treatments. Mild to moderate respiratory weakness, sleep-disordered breathing, and limited cough and secretion control require close follow-up with pulmonologist.
- Will achieve independent sitting but not standing. 75% alive at 25 y old.

**SMA type 3**
- Recognized after 18 mo of age.
- Motor delays, difficulty with climbing stairs, may achieve independent walking but may lose this.
- Progressive symmetric proximal muscle weakness, +/- tremor of hands.
- EMG similar to SMA type 2.
- No curative treatments. Independent ambulation may be achieved, but this skill may be lost. Normal life expectancy.

**SMA type 4**
- Adulthood.
- Clumsy gait.
- Mild progressive proximal muscle weakness.
- EMG similar to SMA type 2; tremor of hands often noted.
- No curative treatment. Physical therapy and assistive devices. No pulmonary issues.
- Slow progression of muscle weakness. Normal life expectancy.

BENIGN ACUTE CHILDHOOD MYOSITIS

Benign acute childhood myositis (myalgia cruris epidemica) is characterized by transient severe muscle pain and weakness affecting mainly the calves and occurring 1–2 days following an upper respiratory tract infection. Although symptoms involve mainly the gastrocnemius muscles, all skeletal muscles appear to be invaded directly by virus; recurrent episodes are due to different viral types. By seroconversion or isolation of the virus, acute myositis has been shown to be largely due to influenza types B and A, and occasionally due to parainfluenza and adenovirus.

MYASTHENIC SYNDROMES

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► Asymmetric, variable weakness, usually coming on or increasing with use (fatigue).
► Involves extraocular, bulbar, and respiratory muscles.
► Positive response to neostigmine and edrophonium.

General Considerations

Myasthenic syndromes are characterized by easy fatigability of muscles, particularly the extraocular, bulbar, and respiratory muscles. In the neonatal period or in early infancy, the weakness may be so constant and general that an affected infant may present nonspecifically as a "floppy infant." Three general categories of myasthenic syndromes are recognized: transient neonatal myasthenia, autoimmune myasthenia gravis, and congenital myasthenia.

Clinical Findings

A. Symptoms and Signs

1. Neonatal (transient) myasthenia—This disorder occurs in 12%–19% of infants born to myasthenic mothers as a result of passive transfer of maternal acetylcholine receptor antibody across the placenta. Neonates present before the third day of life with bulbar weakness, difficulty feeding, weak cry, and hypotonia.

2. Juvenile myasthenia gravis—Like the adult form of myasthenia gravis, autoimmune juvenile myasthenia gravis is characterized by fatigable and asymmetric weakness. However, more than half of patients present with ocular symptoms (ptosis or ophthalmoplegia), unlike adult patients who typically present with limb weakness. Weakness may remain limited to the extraocular muscles in 10%–15% of patients, but approximately half of children develop systemic or bulbar symptoms within 2 years and 75% within 4 years. Symptoms of weakness tend to recur and remit, and can be precipitated by illness or medications such as aminoglycoside antibiotics. Typical signs include difficulty chewing foods like meat, dysphagia, nasal voice, ptosis, ophthalmoplegia, and proximal limb weakness. Other autoimmune disorders such as rheumatoid arthritis and thyroid disease may be associated findings.

3. Congenital myasthenic syndromes—These syndromes are a heterogenous group of hereditary, non-immune disorders of presynaptic, synaptic, or postsynaptic neuromuscular transmission. Patients present with symptoms similar to that of myasthenia gravis, but onset is earlier, before the age of 2 years, and can vary from mild motor delay to dramatic episodic apnea. Serum acetylcholine receptor antibody testing is negative. Response to anticholinesterases is variable, depending on the type of congenital myasthenic syndrome, and some forms may paradoxically worsen. The distinction between this group of disorders and myasthenia gravis is important, as these patients will not benefit from a thymectomy, steroids, or immunosuppressants, but it may be clinically difficult to distinguish between the two.

B. Laboratory Findings

1. Anticholinesterase inhibitor testing

A. NEOSTIGMINE TEST—In newborns and very young infants, the neostigmine test may be preferable to the edrophonium (Tensilon) test because the longer duration of its response permits better observation, especially of sucking and swallowing movements. There is a delay of about 10 minutes before the effect may be manifest. The physician should be prepared to suction secretions, and administer atropine if necessary.
b. **Edrophonium test**—Testing with edrophonium is used in older children who are capable of cooperating in certain tasks and who exhibit easily observable clinical signs, such as ptosis, ophthalmoplegia, or dysarthria. Maximum improvement occurs within 2 minutes. Both cholinesterase inhibitor tests can be limited by patient cooperation and lack of an easily observable clinical sign.

2. **Antibody testing**—Serum acetylcholine receptor binding, blocking, and modulating antibodies typically, though not always, are found in autoimmune juvenile myasthenia gravis. Though not specifically studied in the pediatric population, in the general myasthenia gravis population at large, about 40% of the seronegative patients have muscle-specific receptor tyrosine kinase (MuSK) antibodies. Serum acetylcholine receptor antibodies or MuSK antibodies are often found in the neonatal and juvenile forms. **Intraocular fluid** studies are appropriate.

3. **Genetic testing**—Commercial genetic testing is available for patients with congenital myasthenic syndromes.

C. **Electrophysiologic Studies**
Electrophysiologic studies may be helpful when myasthenic syndromes are considered. Repetitive stimulation of a motor nerve at slow rates of 2–3 Hz with recording over an appropriately chosen muscle reveals a progressive fall in compound muscle action potentials by the fourth to fifth repetition in myasthenic patients. At higher rates of stimulation of 50 Hz, there may be a transient repair of this defect before the progressive decline is seen. Both studies may be technically difficult to perform in infants and younger children as repetitive stimulation can be painful and requires cooperation. If this study is negative, single-fiber EMG in older cooperative children may be helpful diagnostically, but it is technically challenging and time intensive, and requires concentration on the part of the child. Stimulated single-fiber EMG may be performed by trained electromyographers.

D. **Imaging**
Chest radiograph and CT scanning in older children may show thymic hyperplasia. Thymomas are rare in children.

---

**Treatment**

A. **General and Supportive Measures**

In the newborn or in a child in myasthenic or cholinergic crisis (see the following section Complications), supportive care is essential and the child should be monitored in a critical care setting. A careful search for signs of respiratory failure is crucial: simple bedside tests include evaluation of cough and counting to 20 in a single breath. An inability to do either signals respiratory failure. Neck flexion weakness, nasal speech, and drooling are other important signs of respiratory problems. Management of secretions and respiratory assistance should be monitored by trained critical care staff.

B. **Symptomatic Treatment: Anticholinesterase Inhibitors**

1. **Pyridostigmine bromide**—Pyridostigmine is the first-line symptomatic treatment in patients with juvenile myasthenia gravis and mild weakness. Anticholinesterase inhibitors do not modify disease progression but transiently improve muscle strength. For younger children, the starting dose is 0.5–1 mg/kg every 4–6 hours. In older children, the initial dose is 30–60 mg every 4–6 hours. The maximal daily dose is 7 mg/kg/days with an absolute maximum dose of 300 mg/days. The dosage must be adjusted for each patient based on clinical symptoms and side effects. Care must be taken in using this medication in patients suspected of having congenital myasthenic syndrome, as its use could potentially precipitate weakness.

2. **Neostigmine**—Fifteen milligrams of neostigmine are roughly equivalent to 60 mg of pyridostigmine bromide. Neostigmine often causes gastric hypermotility with diarrhea, but it is the drug of choice in newborns, in whom prompt treatment may be lifesaving. It may be given parenterally.

C. **Immunomodulatory Treatment**

Patients with autoimmune myasthenia gravis and more severe weakness not responding to cholinesterase inhibitors alone require long-term treatment with immunomodulation. There are four therapeutic options in this category: (1) plasmapheresis, (2) IVIg, (3) steroids, and (4) immunosuppressants. The mainstay of treatment is steroids, but some patients who either cannot tolerate or do not respond to steroids require treatment with other immunosuppressants such as azathioprine, cyclosporine, or mycophenolate mofetil. Both plasmapheresis and IVIg may be given on a long-term basis, depending on the severity of symptoms, as well as in the acute setting, with myasthenic crises. Special note must be made to the use of steroids, which can transiently worsen symptoms before any benefit is noted, particularly with large starting doses.

D. **Surgical Treatment**

There is less data for efficacy of thymectomy in the pediatric population. Some studies suggest that thymectomy within 2 years of diagnosis results in a higher rate of remission in Caucasian children. Experienced surgical and postsurgical care are prerequisites.
Complications

A. Myasthenic Crisis

Respiratory failure can develop swiftly due to critical weakness of respiratory muscle, bulbar muscles or both, resulting in a myasthenic crisis. Crises are generally not fatal as long as patients receive timely respiratory support and appropriate immunotherapy. Vigilance, however, needs to be maintained as crises can occur in the setting of medical illnesses or surgical procedures. Patients and their caregivers should also be alerted that certain medications can exacerbate myasthenia gravis, including aminoglycoside antibiotics, muscle relaxants, and anesthetics.

B. Cholinergic Crisis

Cholinergic crisis may result from overmedication with anticholinesterase drugs. The resulting weakness may be similar to that of myasthenic crises, and the muscarinic side effects (diarrhea, sweating, lacrimation, miosis, bradycardia, and hypotension) are often absent or difficult to evaluate. If suspected, cholinesterase inhibitors should be discontinued immediately, and improvement afterward suggests cholinergic crisis. As in myasthenic crisis, supportive respiratory care and appropriate immunotherapy should be given.

Prognosis

Prognosis for neonatal (transient) myasthenia is generally good, with complete resolution of symptoms in 2–3 weeks. However, immediate treatment with appropriate respiratory support in the acute presentation period is crucial, primarily because of the risk of secretion aspiration. No further treatment is required thereafter. The prognosis for congenital myasthenic syndromes is variable by subtype. Some subtypes show improvement in weakness with age. Others demonstrate life-threatening episodic apnea, including those with rapsyn mutations, fast-channel mutations, and choline acetyltransferase mutations. Patients with childhood and juvenile myasthenia gravis generally do well, with greater spontaneous remission rates than adult patients. Improvements in respiratory and critical care support has improved prognosis for these patients.

Facial Weakness

Central vs peripheral facial nerve lesions need to be distinguished to determine workup, treatment, and prognosis. The inability to raise the eyebrows indicates peripheral involvement of the facial nerve.

Pathogenesis

The most common cranial mononeuropathy is facial nerve palsy. Cranial nerve VII is a complex nerve that carries several different nerve fibers, including motor fibers to all muscles of facial expression, parasympathetic motor fibers supplying the mucosa of the soft palate and the salivary and lacrimal glands, taste fibers to the anterior two-thirds of the tongue, parasympathetic sensory fibers for visceral sensation from the salivary glands and the nasal and pharyngeal mucosa, and somatic sensory fibers supplying a small part of the external auditory meatus and the skin of the ear. Facial weakness can occur as the result of a lesion anywhere along the path of the nerve. A central lesion such that of a stroke, proximal to the facial nerve nuclei, causes contralateral weakness of the lower face, sparing the forehead and orbicularis oculi muscles which are bilaterally innervated. Peripheral lesions such that of Bell’s Palsy, at or distal to the facial nerve nuclei, cause ipsilateral facial weakness that affects both the upper and lower facial muscles, resulting in an inability to wrinkle the forehead, close the eye or smile. In addition, there may be dysfunction in the ability of tearing and saliva production, hyperacusis, and absent taste sensation over the anterior two-thirds of the tongue.

Clinical Findings

The inability to wrinkle the forehead may be demonstrated in infants and young children by getting them to follow a light moved vertically above the forehead. Loss of taste of the anterior two-thirds of the tongue on the involved side may be demonstrated in cooperative children by age 4 or
5 years. Playing with a younger child and the judicious use of a tongue blade may enable the physician to note whether the child’s face puckers up when something sour (eg, lemon juice) is applied with a swab to the anterior tongue.

**Differential Diagnosis**

Injuries to the facial nerve at birth occur in 0.25%–6.5% of consecutive live births. Forceps delivery is the cause in some cases; in others, the side of the face affected may have abutted in utero against the sacral prominence. Often, no cause can be established.

Acquired peripheral facial weakness (Bell palsy) is common in children. Some cases are postinfectious, although an increasing body of evidence suggests that Bell palsy is a viral-induced cranial neuritis. It may be a presenting sign of Lyme disease, infectious mononucleosis, herpes simplex, or GBS and is usually diagnosable by the history, physical examination, and appropriate laboratory tests. Chronic cranial nerve VII palsy may be a sign of brainstem tumor.

Bilateral facial weakness in early life may be due to agenesis of the facial nerve nuclei or muscles (part of Möbius syndrome) or may even be familial. Myasthenia gravis, Miller-Fisher syndrome, fascioscapulohumeral muscular dystrophy, and myotonic dystrophy must be considered.

Asymmetrical crying facies, in which one side of the lower lip depresses with crying (ie, the normal side) and the other does not, is usually an autosomal dominantly-inherited congenital malformation. The defect in the parent (the asymmetry often improves with age) may be almost inapparent. EMG suggests congenital absence of the depressor angularis muscle of the lower lip. Forceps pressure is often erroneously incriminated as a cause of this innocent congenital anomaly. Occasionally other major (eg, cardiac septal defects) congenital defects accompany the palsy. Congenital unilateral lower lip paralysis with asymmetric crying facies, most often attributed to congenital absence of the depressor anguli oris, is associated with major malformations, most commonly heart defects, in 10% of cases.

**Treatment & Prognosis**

In the vast majority of cases of isolated peripheral facial palsy—both those due to birth trauma and those acquired later—improvement begins within 1–2 weeks, and near or total recovery of function is observed within 2 months. In severe palsy with inefficient blinking, methylcellulose drops, 1%, should be instilled into the eyes to protect the cornea during the day; at night the lid should be taped down with cellophane tape. Upward massage of the face for 5–10 minutes three or four times a day may help maintain muscle tone. Prednisone therapy (2–4 mg/kg orally for 5–7 days) likely does not aid recovery. In the older child, acyclovir or valacyclovir (herpes antiviral agent) therapy or antibiotics (Lyme disease) may have a role in Bell palsy.

In the few children with permanent and cosmetically disfiguring facial weakness, plastic surgical intervention at age 6 years or older may be of benefit. New procedures, such as attachment of facial muscles to the temporal muscle and transplantation of cranial nerve XI, are being developed.

**CHRONIC POLYNEUROPATHY**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

**Insidious onset of weakness and fatigability of the limbs, sometimes with pain or numbness; decreased strength and reflexes.**

**General Considerations**

Polyneuropathy is usually insidious in onset and slowly progressive. Children present with disturbances of gait and easy fatigability in walking or running, and slightly less often, weakness or clumsiness of the hands. Pain, tenderness, or paresthesias are mentioned less frequently. Neurologic examination discloses muscular weakness, greatest in the distal portions of the extremities, with stepgait and depressed or absent deep tendon reflexes. Cranial nerves are sometimes affected. Sensory deficits occur in a stocking-and-glove distribution. The muscles may be tender, and trophic changes such as glassy or parchment skin and absent sweating may occur. Rarely, thickening of the ulnar and peroneal nerves may be felt. In sensory neuropathy, the patient may not feel minor trauma or burns, and thus allows trauma to occur.

The history is crucial in determining whether the cause of a chronic polyneuropathy is genetic or acquired. In the hereditary sensorimotor polyneuropathies, there may be a family history of gait or orthopedics abnormalities but no systemic involvement. Other genetic causes are associated with systemic involvement such those associated with storage disorders or leukodystrophies. A careful history may reveal an exposure to toxins known to cause neuropathies such as lead or arsenic, or use of medications such as vincristine.
Neuropathies can be the late manifestations of systemic disorders like diabetes and autoimmune disorders. This chronic inflammatory demyelinating neuropathy (CIDP) is assumed to be immunologically mediated and may have a relapsing course. Sometimes facial weakness occurs. CSF protein levels are elevated. NCV is slowed, and findings on nerve biopsy are abnormal. Immunologic abnormalities are seldom demonstrated, although nerve biopsy findings may show round cell infiltration. Corticosteroids, repeated IVIg, and, occasionally, immunosuppressants may give long-term benefit.

**Clinical Findings**

Hereditary neuropathy is the most common documented cause of chronic neuropathy in childhood. A careful genetic history (pedigree) and examination and electrical testing (motor and sensory nerve conduction and EMG) of patient and relatives are keys to diagnosis. Genetic tests are available for many of the variants. Nerve biopsy is rarely necessary.

Other hereditary neuropathies may have ataxia as a prominent finding, often overshadowing the neuropathy. Examples are Friedreich ataxia, adrenoleukodystrophy, and Krabbe disease. Finally, some hereditary neuropathies are associated with identifiable and occasionally treatable metabolic errors (see Tables 25–21 and 25–22). These disorders are described in more detail in Chapter 36.

Laboratory diagnosis of chronic polyneuropathy is made by electrophysiologic testing with EMG/NCS. CSF protein levels can be elevated, sometimes with an increased IgG index. Nerve biopsy, with teasing of the fibers and staining for metachromasia, may demonstrate loss of myelin, and to a lesser degree, loss of axons and increased connective tissue or concentric lamellas (so-called onion bulb appearance) around the nerve fiber. Muscle biopsy may show the pattern associated with denervation. Other laboratory studies directed toward specific causes mentioned above include screening for heavy metals and for metabolic, renal, or vascular disorders.

**Treatment & Prognosis**

Therapy is directed at specific disorders whenever possible. Corticosteroid therapy is used first when the cause is unknown or neuropathy is considered to be due to chronic inflammation (this is not the case in acute GBS [AIDP; acute inflammatory demyelinating neuropathy]). Prednisone is initiated at 2–4 mg/kg/days orally, with tapering to the lowest effective dose; it may need to be re instituted when symptoms recur. Prednisone should not be used for treatment of hereditary neuropathy. Immunomodulating therapy may be safer or “steroid-sparing”; IVIg, plasmapheresis, mycophenolate mofetil, and rituximab are choices.

The long-term prognosis varies with the cause and the ability to offer specific therapy. In the corticosteroid-dependent group, residual deficits are more frequent.

*See elsewhere in text for manifestations.*
elbows and slightly abducted, and the knees partly flexed. The “floppy” infant droops over the hand like an inverted U. The normal newborn attempts to keep the head in the same plane as the body when pulled up from supine to sitting by the hands (traction response). Marked head lag is characteristic of the floppy infant. In vertical suspension, the hypotonic infant will slip through the examiner’s hands when held under the armpits. Hyperextensibility of the joints is not a dependable criterion.

B. Laboratory Findings
A general rule for laboratory testing is to localize the etiology of the hypotonia. For instance, if a lower motor neuron etiology is suspected, a serum CK, EMG/NCS, and/or muscle biopsy may be appropriate as first tier testing. Many neuromuscular disorders may be diagnosed by clinical findings alone, as is often the case with spinal muscular atrophy and congenital myotonic dystrophy, and in those cases, genetic testing is often the first testing warranted. If the hypotonic is accompanied by language or cognitive delay, a CNS or genetic disorder is most likely, and MR imaging of the brain may be the most useful diagnostic test.

Differential Diagnosis
The most common etiology of hypotonia in the neonate is hypoxic-ischemic encephalopathy. Dysmorphic features may suggest a genetic etiology such as Down syndrome and Prader-Willi syndrome. Abnormalities of the hair or skin, which form from the neuroectoderm in development with the brain, may prompt an evaluation for brain malformations. Often seizures or language or cognitive delay may be accompanying features. Regression in development is often a clue for mitochondrial or metabolic disorders. Neuromuscular disorders including congenital myotonic dystrophy and spinal muscular atrophy can present as hypotonia in the infant. While the list of differential diagnosis in Table 25–22 is not complete, it describes the clinical features of some of the more common causes of hypotonia in infants and children.

Treatment
Treatment for many of these disorders is supportive. Physical and occupational therapy can facilitate some progress to a varying degree. Accompanying seizures and other systemic manifestations should be controlled to optimize development.

Web Resources
Provides both adult and child neurology practice parameters.
Includes general information about epilepsy, and a comprehensive section about antiepileptic drugs.
Describes resources and tests related to child neurology and provides a comprehensive list of child neurology–related website links.
Provides research updates and organizational information and has child neurology–specific practice parameters.
Cure CMD: http://curecmd.org/.
Includes tutorials about epilepsy and living with epilepsy.
Provides detailed information about available genetic testing, research, literature/disorder reviews, and resources for most genetically determined neurologic disorders.
Contains research updates, organizational information, and detailed information regarding neuromuscular disorders.
Provides brief descriptions of neurologic disorders, related research, research opportunities, and relevant organizations.
National Ataxia Foundation http://www.ataxia.org/.
Resource for providers and patients with ataxia including research and support groups.

Contains detailed information for parents and providers about Tuberous Sclerosis.
Descriptions of movement disorders, related research, and research opportunities.
Orthopedics

Orthopedics is the medical discipline that deals with disorders of the musculoskeletal system. Patients with orthopedic problems generally present with one or more of the following complaints: pain, swelling, loss of function, or deformity. While the history reveals the patient’s expectation, physical examination and radiographic imaging are vitally important features of orthopedic diagnosis.

**DISTURBANCES OF PRENATAL ORIGIN**

**ESSENTIALS OF DIAGNOSIS & TREATMENT**

- Conditions are present at birth (congenital).
- Multiple organ systems may be involved.
- Treatment is aimed at maximizing function.

**CONGENITAL AMPUTATIONS & LIMB DEFICIENCIES**

**Clinical Findings**

**A. Symptoms and Signs**

The specific etiology of many congenital amputations is not clear, but a genetic association has been suggested. Some congenital amputations may be due to teratogens (eg, drugs or viruses), amniotic bands, or metabolic diseases (eg, maternal diabetes). Limb deficiencies are rare with an overall prevalence for all types of limb deficiencies of 0.79 per 1000. The most common cause of limb deficiencies is vascular disruption defects (prevalence of 0.22 per 1000). As a group, upper limb deficiencies occur more frequently than lower limb deficiencies, but the single most frequent form of limb deficiency is congenital longitudinal deficiency of the fibula. Children with congenital limb deficiencies generally also have a high incidence of other congenital anomalies, including genitourinary, cardiac, and palatal defects. Deficiencies have a wide spectrum, ranging from mild limb length discrepancy to significant deformity. They usually consist of a partial absence of structures in the extremity along one side. For example, in radial club hand, the entire radius is absent, but the thumb may be either hypoplastic or completely absent. The effect on structures distal to the deficiency varies. Complex tissue defects are virtually always associated with longitudinal bone deficiency since associated nerves and muscles are not completely represented when a bone is absent.

**Treatment**

The overall goal of treatment is to achieve a functional extremity. If the deficiency is in a weight-bearing limb, the goal is to ensure equal loading after treatment. Limb lengthening and/or contralateral limb shortening can be used to treat less severe deficiencies. More severe deficiencies are treated with a prosthesis or orthosis to compensate for the length discrepancy. For certain severe anomalies, operative treatment to remove a portion of the malformed extremity (eg, foot) is indicated to allow for early prosthetic fitting. In these instances, early prosthetic fitting allows for maximization of function.

Typically, a lower extremity prosthesis would be fit at about 1 year of age allowing the child to begin ambulation at an appropriate developmental age. The prosthesis is well accepted since it becomes necessary for balancing and walking. In unilateral upper extremity amputation, the child benefits from the use of a passive mitten-type prosthesis starting as early as 6 months of age. Early fitting has the advantage of instilling an accustomed pattern of proper length and
bimanual manipulation. Although myoelectric prostheses have a technologic appeal, the majority of patients find the simplest construct to be the most functional. Children quickly learn how to function with their prostheses and can lead active lives.

**DEFORMITIES OF THE EXTREMITIES**

**ESSENTIALS OF DIAGNOSIS & TREATMENT**

► Many represent normal physiologic growth patterns.
► Key to diagnosis is recognition of abnormal patterns that deviate from normal development.
► Treatment is varied depending on condition.

**COMMON FOOT PROBLEMS**

**Metatarsus Adductus**

► Clinical Findings

A. Symptoms and Signs

Metatarsus adductus, a common congenital foot deformity, is characterized by inward deviation of the forefoot. It is the most common foot abnormality, observed in newborns at a rate of 1–2 per 1000 live births. When the deformity is more rigid, it is characterized by a vertical crease in the medial aspect of the arch. Angulation occurs at the base of the fifth metatarsal causing prominence of this bone. Most flexible deformities are secondary to intrauterine positioning and usually resolve spontaneously. Several investigators have noticed that 10%–15% of children with metatarsus adductus have hip dysplasia; therefore, a careful hip examination is necessary. The etiology of rigid deformities is unknown.

► Treatment

Fully flexible deformity requires no treatment. If the deformity is rigid and cannot be manipulated past the midline, it is worthwhile to perform serial casting, with cast changes in 1- to 2-week intervals, to correct the deformity. Orthoses and corrective shoes do not improve symptoms; however, they can be used to maintain the correction obtained by casting.

**Clubfoot (Talipes Equinovarus)**

► Clinical Findings

A. Symptoms and Signs

Classic talipes equinovarus, or clubfoot, requires three features for diagnosis: (1) plantar flexion of the foot at the ankle joint (equinus), (2) inversion deformity of the heel (varus), and (3) medial deviation of the forefoot (adductus) (Figure 26–1). Clubfoot occurs in approximately 1 per 1000 live births. The three major categories of clubfoot are idiopathic, neurogenic, and those associated with syndromes such as arthrogryposis and Larsen syndrome. Infants with a clubfoot should be examined carefully for associated anomalies, especially of the spine. Idiopathic club foot may be hereditary.

► Treatment

Manipulation of the foot to stretch the contracted tissues on the medial and posterior aspects, followed by casting to hold the correction is the preferred treatment. Serial castings are typically performed on a weekly basis for 6–8 weeks. When instituted shortly after birth, correction is rapid. If treatment is delayed, the foot tends to become more rigid within a matter of days. Casting treatment requires patience...
and experience, but fewer patients require surgery when attention is paid to details of the Ponseti technique. If there is remaining equinus, surgery may be required in the form of a percutaneous Achilles tenotomy in order to achieve full correction. After full correction is obtained, a night brace is necessary for long-term maintenance of correction. Recent studies indicate that there is poor compliance with brace use following intervention with the Ponseti technique; however, many patients undergoing this treatment are able to independently ambulate only 2 months later than infants with no deformity. The French method is another nonsurgical method of treatment, which is commonly performed by physical therapists. The feet are stretched and manipulated several times per week and a combination of taping and a plastic splint are used to hold the correction after each session. If the foot is rigid and resistant to correction through the Ponseti or French techniques, extensive surgical release and correction are occasionally needed to improve the functional position of the foot. Approximately 15%–50% of patients require a surgical release.

Flatfoot

► Clinical Findings

A. Symptoms and Signs

Flatfoot is normal in infants. If the heel cord is of normal length, full dorsiflexion is possible when the heel is in the neutral position. As long as the heel cord is of normal length and a longitudinal arch is noted when the child is sitting in a non-weight-bearing position, a normal arch will generally develop.

Younger children who are male, obese, and have excessive joint laxity are more likely to be flatfooted. Around 15% of flatfeet do not resolve spontaneously. There is usually a familial incidence of relaxed flatfeet in children who have no apparent arch. In any child with a shortened heel cord or stiffness of the foot, other causes of flatfoot such as tarsal coalition (congenital fusion of the tarsal bones) should be ruled out by a complete orthopedic examination, radiographs and advanced imaging.

► Treatment

For an ordinary correctable flatfoot, no active treatment is indicated unless calf or leg pain is present. In children who have leg pains attributable to flatfoot, a supportive shoe, such as a good-quality sports shoe, is useful. An orthotic that holds the heel in neutral position and supports the arch may relieve discomfort if more support is needed. An arch insert should not be prescribed unless passive correction of the arch is easily accomplished; otherwise, the skin over the medial side of the foot will be irritated. Surgical correction can be done; however, surgery has been found to only improve symptoms associated with shoe or brace wear such as pain, calluses or skin breakdown, with limited improvement of the planovalgus deformity.

Talipes Calcaneovalgus

► Clinical Findings

A. Symptoms and Signs

Talipes calcaneovalgus is characterized by excessive dorsiflexion at the ankle and eversion of the foot (Figure 26–2). This disorder can be associated with posteroomedial bowing of the tibia and is due to intrauterine position and is often present at birth. The deformity occurs in 0.4–1 per 1000 live births.

► Treatment

Treatment consists of passive exercises, such as stretching the foot into plantar flexion. With or without treatment,
the deformity usually resolves by age 3–6 months. In rare instances, it may be necessary to use plaster casts to help with manipulation and positioning. Complete correction is the rule.

Cavus Foot

Clinical Findings

A. Symptoms and Signs

Cavus foot consists of an unusually high longitudinal arch of the foot. It may be hereditary or associated with neurologic conditions such as poliomyelitis, hereditary sensory motor neuropathies, tethered spinal cord, and diastematomyelia (congenital splitting of the spinal cord). Typically there is an associated contracture of the toe extensors, producing a claw toe deformity in which the metatarsal phalangeal joints are hyperextended and the interphalangeal joints acutely flexed. Cavus foot presents with diffuse and localized pain in the lower legs and is commonly associated with an inflexible foot deformity. Any child presenting with progressive cavus feet should receive a careful neurologic examination as well as radiographs and magnetic resonance imaging (MRI) of the spine.

Treatment

Conservative therapy, such as an orthotic to realign the foot, can be effective in milder cases. In symptomatic cases, surgery may be necessary to lengthen the contracted extensor and flexor tendons and to release the plantar fascia and other tight plantar structures, but tethered cord or other spinal anomalies should be addressed first. Associated varus heel deformities cause more problems than the high arch.

Bunions (Hallux Valgus)

Clinical Findings

A. Symptoms and Signs

With a prevalence of 23%–35%, hallux valgus is the most common forefoot deformity. The etiology is unknown. Adolescents may present with lateral deviation of the great toe associated with a prominence over the head of the first metatarsal. Around 60% of patients have a family history of this condition. The deformity is painful with shoe wear and almost always relieved by fitting shoes that are wide enough in the toe area. Since further growth tends to cause recurrence of the deformity, surgery should be avoided in the adolescent.

Treatment

Therapeutic treatments are aimed at correcting the muscular and weight-bearing forces that act on the joint. While conservative treatment provides symptomatic relief, it does not reverse the natural history, as these deformities will typically continue to progress until corrected surgically. A high percentage of these patients ultimately have surgery in adulthood due to a continued progression of the deformity. Surgical treatment should be delayed until the patient is mature, due to the risk of remodeling and recurrence of deformity. Surgery leads to satisfactory outcomes in 95% of patients.

GENU VARUM & GENU VALGUM

Clinical Findings

A. Symptoms and Signs

Genu varum (bowleg) is normal from infancy through 3 years of age. The alignment then changes to genu valgum (knock-knee, Figure 26–3) until about age 8 years, at which time adult alignment of 5–9 degrees of anatomic valgus is attained. If bowing persists beyond age 2, increases rather than decreases, occurs in only one leg, or if a patient is...
knock-kneed in association with short stature, the patient should be referred to an orthopedist. Genu varum is usually secondary to tibial rotation (Blount disease, Figure 26–4), while genu valgum may be caused by skeletal dysplasia or rickets.

**Treatment**

Individuals with genu varum may be at a greater risk for falling as the deformity increases the normal postural sway in the mediolateral direction. Bracing may be appropriate. An osteotomy may be necessary for severe problems such as occurs in Blount disease (proximal tibial epiphysial dysplasia).

**TIBIAL TORSION & FEMORAL ANTEVERSION**

**Clinical Findings**

**A. Symptoms and Signs**

“Toeing in” in small children is a common parental concern. Tibial torsion refers to rotation of the leg between the knee and the ankle. Internal rotation amounts to about 20 degrees at birth but decreases to neutral rotation by age 16 months. The deformity may be accentuated by laxity of the knee ligaments, which allows excessive internal rotation of the leg in small children. This condition is largely self-limiting and usually resolves spontaneously with further growth and development. Toeing in beyond age 2 or 3 years is usually secondary to femoral anteversion, characterized by more internal rotation of the hip than external rotation. This femoral alignment decreases toward neutral during growth.

**Treatment**

Treatment for tibial torsion is focused on educating the families to the benign nature and expected resolution with observation. In older children suspected to have femoral anteversion, there is no long-term improvement with treatment with shoes or braces. Osteotomy for rotational correction is occasionally required when symptoms such as knee and hip pain are present. However, the vast majority go on to resolve spontaneously.

**DEVELOPMENTAL DYSPLASIA OF THE HIP JOINT**

**Clinical Findings**

Developmental dysplasia of the hip (DDH) encompasses a spectrum of conditions where an abnormal relationship exists between the proximal femur and the acetabulum. In the most severe condition, the femoral head is not in contact with the acetabulum and is classified as a *dislocated hip*. In a *dislocatable hip*, the femoral head is within the acetabulum but can be dislocated with a provocative maneuver. A *subluxatable hip* is one in which the femoral head comes partially out of the joint with a provocative maneuver. Acetabular dysplasia is used to denote insufficient acetabular development and is a radiographic diagnosis. Congenital dislocation of the hip more commonly affects the left hip, occurring in approximately 1%–3% of newborns. At birth, both the acetabulum and femur are underdeveloped (Figure 26–5).

**A. Symptoms and Signs**

Clinical diagnosis of dislocations in newborns is dependent on demonstrating the instability of the joint by placing the infant on his or her back and obtaining complete relaxation. As these clinical signs can be subtle, they can be easily missed with a crying or upset infant. The examiner’s long finger is placed over the greater trochanter and the thumb over the inner side
of the thigh. Both hips are flexed 90 degrees and then slowly abducted from the midline, one hip at a time. With gentle pressure, an attempt is made to lift the greater trochanter forward. A feeling of slipping as the head relocates is a sign of instability (Ortolani sign). When the joint is more stable, the deformity must be provoked by applying slight pressure with the thumb on the medial side of the thigh as the thigh is adducted, thus slipping the hip posteriorly and eliciting a palpable clunk as the hip dislocates (Barlow sign, Figure 26–6). Limited hip abduction of less than 60 degrees while the knee is in 90 degrees of flexion is believed to be the most sensitive sign for detecting a dysplastic hip. Asymmetrical skin folds are present in about 25% of normal newborns and therefore are not particularly helpful to diagnosing hip dislocation. The signs of instability become less evident after the first month of life. If the knees are at unequal heights when the hips and knees are flexed, the dislocated hip will be on the side with the lower knee. This is called a Galeazzi sign. If dysplasia of the hip has not been diagnosed before the child begins to walk, there will be a painless limp and/or a lurch to the affected side. When the child stands on the affected leg, a dip of the pelvis will be evident on the opposite side, due to weakness of the gluteus medius muscle. This is called the Trendelenburg sign and accounts for the unusual swaying gait. As a child with bilateral dislocation of the hips begins to walk, the gait is waddling.

B. Imaging Studies

Clinical signs of instability are more reliable than radiographs for diagnosing developmental dislocation of the hip in the newborn. Ultrasonography is most useful in newborns, and can be helpful for screening high-risk infants, such as those with breech presentation or positive family history. Radiological examination becomes more valuable after the first 6 weeks of life, with lateral displacement of the femoral head being the most reliable sign. In children with incomplete abduction during the first few months of life, a radiograph of the pelvis is indicated.

**Treatment**

Dysplasia is progressive with growth unless the instability is corrected. If the dislocation is corrected in the first few weeks of life, the dysplasia can be completely reversible and a normal hip will more likely develop. If the dislocation or subluxation persists with age, the deformity will worsen until it is not completely reversible, especially after the walking age. For this reason, it is important to diagnose the deformity and institute treatment early.

A Pavlik harness, which maintains reduction by placing the hip in a flexed and abducted position, can be easily used to treat dislocation or dysplasia diagnosed in the first few weeks or months of life (Figure 26–7). In order to be safely treated in a Pavlik harness, hips must be manually reducible with only gentle manipulation. Forced abduction, or reduction requiring extremes of motion for stability, can lead to avascular necrosis of the femoral head and is contraindicated. The use of double or triple diapers is ineffective. An orthopedic surgeon with experience managing the problem is best to supervise treatment.

If a hip cannot be reduced and have a stable reduction with Pavlik treatment, then a closed reduction with arthrogram is appropriate treatment. A hip spica cast is used after reduction. If the hip is not stable within a reasonable range of motion after closed reduction, open reduction is indicated.

Treatment is still possible in the first 2 years of life, but the results are not as good as with early treatment. In patients older than 2 years, more aggressive procedures like osteotomies and operations to correct the deformities of the acetabulum and femur, as well as open reduction, are often necessary to create a more normal orientation and shape.
of the hip joint. Older children, as well as children who are bilaterally affected, are more likely to experience complications from more extensive procedures.

Novais EN, Sanders J, Kestel LA, Carry PM, Meyers ML: Graf Type-IV hips have a higher risk of residual acetabular dysplasia at 1 year of age following successful Pavlik harness treatment for developmental hip dysplasia. J Pediatr Orthop 2016; [PMID: 27662383].

**SLIPPED CAPITAL FEMORAL EPIPHYSIS**

**A. Symptoms and Signs**

Slipped capital femoral epiphysis (SCFE) is caused by displacement of the proximal femoral epiphysis due to disruption of the growth plate (Figure 26–8). The head of the femur is usually displaced medially and posteriorly relative to the femoral neck. This condition is most commonly seen in adolescent, obese males. It occurs when stress increases across the proximal femoral physis (growth plate) or resistance to shear is reduced. Factors that can lead to this increase in stress or decrease in resistance include endocrine disorders, obesity, coxa profunda (a deep acetabular socket), and femoral or acetabular retroversion. Retroversion of the femur occurs when the proximal femoral segment is angled posteriorly relative to the shaft of the femur. Acetabular retroversion refers to when the alignment of the opening of the acetabulum does not face the normal anterolateral direction, but inclines more posterolaterally.

Clinically, SCFE is classified as stable or unstable. SCFE is considered stable if the child is able to bear weight on the affected extremity. In unstable SCFE, the child is unable to bear weight. An increased rate of avascular necrosis is correlated with the inability to bear weight.

Acute SCFE occasionally occurs following a fall or direct trauma to the hip. More commonly, vague symptoms occur over a protracted period in an otherwise healthy child who presents with pain and limp. The pain can be referred into the thigh or the medial side of the knee, making examination of the hip joint important in any obese child complaining of knee pain. Physical examination consistently reveals a limitation of internal rotation of the hip. The diagnosis may be clearly apparent only in the lateral radiographic view of the hip or frog lateral of the pelvis.

**Treatment**

Initial management consists of making the patient non-weight bearing on crutches and immediate referral to an orthopedic surgeon. Treatment is based on the same principles that govern treatment of any fracture of the femoral neck: the head of the femur is internally fixated in situ to the neck of the femur and the physeal fracture allowed to heal. In situ fixation without closed reduction is considered the standard of care for SCFE treatment due to the high risk of AVN of the femoral head associated with attempted closed reduction. For a SCFE that is significant in terms of displacement, specialized centers are beginning to perform open reduction through a surgical dislocation of the hip, but due to the risk
of avascular necrosis of the femoral head, this should only be employed by an orthopedic surgeon with experience in this procedure.

» Prognosis

The long-term prognosis is guarded because most of these patients continue to be overweight and overstress their hip joints. Follow-up studies have shown a high incidence of premature degenerative arthritis, even in those who do not develop avascular necrosis. The development of avascular necrosis almost guarantees a poor prognosis, because new bone does not readily replace the dead bone at this late stage of skeletal development. About 30% of patients have bilateral involvement, which may occur as late as 1 or 2 years after the primary episode.

COMMON SPINE CONDITIONS

ESSENTIALS OF DIAGNOSIS & TREATMENT

» Conditions most often present with a neck or back deformity.
» Treatment varies and is based on risk factors for progression.

TORTICOLLIS

» Clinical Findings

A. Symptoms and Signs

Injury to the sternocleidomastoid muscle during delivery or disease affecting the cervical spine in infancy, such as congenital vertebral anomalies, may cause torticollis. When contracture of the sternocleidomastoid muscle causes torticollis, the chin is rotated to the side opposite of the affected muscle, causing the head to tilt toward the side of the contracture (Figure 26–9). A mass felt in the midportion of the sternocleidomastoid muscle in a newborn is likely a hematoma or developmental fibroma, rather than a true tumor.

Acute torticollis may follow upper respiratory infection or mild trauma in children. Upper respiratory infections may lead to swelling in the upper cervical spine, particularly at the C1-C2 region. This swelling renders the C1-C2 articulation susceptible to rotatory subluxation, which commonly presents as a clinical picture of torticollis. Rotatory subluxation of the upper cervical spine requires computed tomography for accurate assessment. Other causes of torticollis include spinal cord and cerebellar tumors, syringomyelia, and rheumatoid arthritis.

» Treatment

If torticollis in early infancy is left untreated, a striking facial asymmetry can persist. Passive stretching is an effective treatment in up to 97% of all cases. If the deformity does not correct with passive stretching during the first year of life, surgical release of the muscle origin and insertion can be an effective treatment option. Excising the “tumor” of the sternocleidomastoid muscle is unnecessary and creates an unsightly scar.

For acquired torticollis in childhood, traction or a cervical collar usually results in resolution of the symptoms within 1 or 2 days.

» Prognosis

Torticollis is occasionally associated with congenital deformities of the cervical spine. Radiographs of the spine are indicated in most cases where such anomalies are suspected. In addition, there is a 15%–20% incidence of associated hip dysplasia.

SCOLIOSIS

Scoliosis is characterized by lateral curvature of the spine associated with rotation of the involved vertebrae and classified by its anatomic location, in either the thoracic or lumbar spine, with rare involvement of the cervical spine (Figure 26–10). There are four main categories of scoliosis: idiopathic, congenital, neuromuscular (associated with a neurological or muscular disease), and syndromic (associated with a known syndrome). Idiopathic scoliosis accounts for around 80% of cases. It is more common in girls and typically develops around 10–12 years of age, but can occur earlier. There is a genetic component, but the etiology is multifactorial. Congenital scoliosis accounts for 5%–7% of cases and is a result of vertebral abnormalities due to a failure of formation or segmentation of the affected vertebrae.

Clinical Findings

A. Symptoms and Signs

Scoliosis in adolescents does not typically cause significant pain. If a patient has significant pain, she/he should be evaluated to rule out the possibility of some other disorder such as infection or tumor. Deformity of the rib cage and asymmetry of the waistline are clinically evident for curvatures of 30 degrees or more. Lesser curves may be detected through a forward bending test, which is designed to detect early abnormalities of rotation that may not be apparent when the patient is standing erect. Rotation of the spine may be measured with a scoliometer. Rotation is associated with a marked rib hump as the lateral curvature increases in severity.

B. Imaging

Radiographs taken of the entire spine in the standing position in both the posterior anterior (PA) and lateral planes are the most valuable for diagnosis (see Figure 26–10). Usually, a primary curve is evident with compensatory curvature to balance the body.

Treatment

Treatment of scoliosis depends on the curve magnitude, skeletal maturity, and risk of progression. Specific management is dependent on the Cobb angle, measured on a standing PA x-ray of the spine. Curvatures of less than 20 degrees typically do not require treatment unless they show progression. Bracing is indicated for curvatures of 20–40 degrees in a skeletally immature child. Curvatures greater than 40 degrees are resistant to treatment by bracing. Thoracic curvatures greater than 70 degrees have been correlated with poor pulmonary function in adult life, leading treatment algorithms toward preventing progression to this extreme. Curvatures reaching a magnitude of 40–60 degrees are indicated for surgical correction as they are highly likely to continue to progress. Surgical intervention consists of spinal instrumentation and fusion. Spinal instrumentation (rods, screws, hooks, etc.) are applied to the region of the spine to be corrected and bone graft is added. Definitive spinal fusions should be delayed as long as possible in young children through the use of casting, bracing, and growth modulating surgeries such as growing rods or vertical expandable prosthetic titanium ribs (VEPTR).

Prognosis

Compensated small curves that do not progress may cause minor deformities but are well tolerated throughout life. Patients should be counseled about the genetic transmission of scoliosis and cautioned that their children’s backs should be examined as part of routine physicals. Early detection allows for simple brace treatment. Severe scoliosis may require correction by spinal fusion.

KYPHOSIS

Clinical Findings

A. Symptoms and Signs

When looking at the sagittal view of a spine, there are two normal curves to be noticed. In the lumbar region, the normal curve with an anterior convexity is known as lumbar lordosis. In the thoracic region, a normal curve with a posterior convexity is called kyphosis. Excessive kyphosis is pathologic and known as hyperkyphosis. Clinically, a visible deformity may be visible on the back, exacerbated by the forward bend test (Figure 26–11). Kyphosis can often accompany scoliosis, in which case the two conditions may share a common etiology. Additionally, excessive kyphosis can be caused by trauma and degenerative and inflammatory conditions. Congenital and developmental abnormalities,
including Scheuermann disease, are the most common cause of severe kyphosis. In congenital kyphosis, abnormal vertebrae arise from either a failure of segmentation or formation and commonly result in wedge-shaped vertebrae that cause severe kyphosis.

**B. Imaging**

Standing radiographs taken in the lateral plane are necessary to measure the angle of the curve of the spine and quantify the severity of the curve. The curve is typically measured across the thoracic region from T1 to T12. Normal values for this measurement fall in the 20–45 degree range. Anything in excess of 45 degrees is considered pathologic (Figure 26–12).

**Treatment**

Treatment for kyphosis is similar to that of scoliosis. Mild forms of the deformity may undergo treatment with bracing. Depending on etiology, however, the effectiveness and indications for doing so are fraught with mixed results. Surgical intervention with spinal instrumentation and fusion may be indicated for more severe deformities. In patients who have congenital, wedge-shaped abnormal vertebrae, vertebral column resection may be indicated.

**INFLAMMATORY CONDITIONS**

**ESSENTIALS OF DIAGNOSIS & TREATMENT**

- Chronic conditions generally related to overuse.
- Rule out more serious conditions first.
- Activity restriction is the treatment.

**ARTHRITIS & TENOSYNOVITIS**

**Clinical Findings**

**A. Symptoms and Signs and Treatment**

Degenerative arthritis may follow childhood skeletal problems, such as infection, SCFE, avascular necrosis, trauma, or hemarthroses in patients with hemophilia. Early, effective treatment of these disorders can prevent arthritis. Overuse in young athletes can also cause degenerative changes to the soft tissues around the joints. Young boys throwing excessive numbers of pitches, especially curve balls, may develop "Little League" elbow, consisting of degenerative changes around the humeral condyles associated with pain, swelling, and limitation of motion (see Chapter 27). Limitation of the number of pitches thrown by little league pitchers is the key to prevention.

Tenosynovitis is most common in the knees and feet. Children taking dancing lessons, particularly toe dancing, may have pain around the flexor tendon sheaths in the toes or ankles. Rest is effective treatment. Around the knee, the patellar ligament may be irritated, with associated swelling in the infrapatellar fat pad. Synovitis in this area is usually due to overuse and is treated by rest and nonsteroidal anti-inflammatory drugs. Corticosteroid injections are contraindicated.
SYNDROMES WITH MUSCULOSKELETAL INVOLVEMENT

ESSENTIALS OF DIAGNOSIS & TREATMENT

- Many genetic syndromes include a musculoskeletal component or association.
- Resulting deformity can result in a lack of function.

ARTHROGRYPOSIS MULTIPLEX CONGENITA (AMYOPLASIA CONGENITA)

- Clinical Findings

A. Symptoms and Signs

Arthrogryposis multiplex congenita (AMC) consists of incomplete fibrous ankylosis (usually bilateral) of many or all joints of the body. AMC affects both genders equally and occurs in approximately 1 in 2–3000 live births. Upper extremity contractures usually consist of adduction of the shoulders; extension of the elbows; flexion of the wrists; and stiff, straight fingers with poor muscle control of the thumbs. Common deformities of the lower extremities include dislocation of the hips, extension contractures of the knees, and severe club feet. The joints are fusiform and the joint capsules decreased in volume due to lack of movement during fetal development. Muscle development is poor and may be represented only by fibrous bands. Various investigations have attributed the basic defect to an abnormality of muscle or lower motor neurons.

- Treatment

Passive mobilization of joints is the early treatment. Prolonged casting results in further stiffness and is not indicated. Removable splints combined with vigorous therapy are the most effective conservative treatment; however, surgical release of the affected joints is often necessary. Clubfoot associated with arthrogryposis is very stiff and nearly always requires surgical correction. Knee surgery, including capsulotomy, osteotomy, and tendon lengthening, is used to correct deformities. In young children, a dislocated hip may be reduced operatively by a medial approach. Multiple operative hip procedures are contraindicated, as they may further stiffen the hip dislocation with consequent impairment of motion. Osteotomies are successful in treating some deformities by improving mechanical alignment to improve the function of a lower extremity. Affected children are often able to walk despite dislocations and contractures, but functional gait improves with treatment. The long-term prognosis for physical and vocational independence is guarded. These patients have normal intelligence, but they have such severe physical restrictions that gainful employment is hard to find.

Marfan Syndrome

- Clinical Findings

A. Symptoms and Signs

Marfan syndrome is a connective tissue disorder characterized by unusually long fingers and toes (arachnodactyly); hypermobility of the joints; subluxation of the ocular lenses; other eye abnormalities, including cataract, coloboma, megalocornea, strabismus, and nystagmus; a high-arched palate; a strong tendency to scoliosis; pectus carinatum (an outward protrusion of the sternum); and thoracic aortic aneurysms due to weakness of the media of the vessels (see Chapter 37). Fibrillin-1 gene mutations are commonly associated with Marfan syndrome. Serum mucoproteins may be decreased, and urinary excretion of hydroxyproline increased. The condition is easily confused with homocystinuria, because the phenotypic presentation is nearly identical. The two diseases are differentiated by detecting homocystine in the urine of patients with homocystinuria.

- Treatment

Treatment is usually supportive and includes management of blood pressure and restriction of physical activity. Scoliosis may require more vigorous treatment by bracing or spine fusion. The long-term prognosis has improved for patients since the development of better treatment of their aortic aneurysms.

Dietz HC: Marfan syndrome. GeneReviews 2017; Internet: [PMID: 20301510].

KLIPPEL-FEIL SYNDROME

- Clinical Findings

A. Symptoms and Signs

Klippel-Feil syndrome is characterized by failure of segmentation of some or all of the cervical vertebrae.
Multiple congenital spinal anomalies may be present, with hemivertebrae and scoliosis among the most common presentations. The neck is short and stiff, the hairline is low, and the ears are low set. Cervical rib, spina bifida, torticollis, web neck, high scapula, renal anomalies, and deafness are commonly associated defects. Renal ultrasound as well as a hearing test is indicated if there is evidence of abnormal renal function.

**Treatment**

Surgical intervention is necessary to prevent neurologic injury in symptomatic patients who present with unstable spinal anomalies. If asymptomatic, a spine surgeon will determine if surgical intervention is warranted after review of patient’s age, history, and activity level. Spinal arthrodesis is indicated if progressive scoliotic deformities develop.

**Sprengel Deformity**

**Clinical Findings**

**A. Symptoms and Signs**

Sprengel deformity is a congenital condition where one or both scapulas are elevated and hypoplastic. The deformity prevents the arm from raising completely on the affected side, and torticollis may be an associated finding. The deformity occurs alone or in association with Klippel-Feil syndrome or scoliosis and rib abnormalities. If the deformity is functionally limiting, the scapula may be surgically relocated closer to the normal anatomic position. Surgical intervention improves cosmetic appearance and function.

**Osteogenesis Imperfecta**

**Clinical Findings**

**A. Symptoms and Signs**

Osteogenesis imperfecta is a rare genetic connective tissue disease characterized by multiple and recurrent fractures. The estimated incidence is 1 in 12,000–15,000. Clinical features of the disease lead to diagnosis in the majority of cases. There are several forms of osteogenesis imperfecta, designated type I to type XII. Types I–V are the result of autosomal dominant mutations, whereas types VI–XII are autosomal recessive. Each type is associated with a mutation of a different gene, varying levels of severity, and a range of characteristic features. The severe fetal type (osteogenesis imperfecta congenita) is distinguished by multiple intrauterine or perinatal fractures. Moderately affected children have numerous fractures and exhibit dwarfism as a result of their acquired bone deformities and growth retardation. Fractures begin to occur at different times and in variable patterns after the perinatal period, resulting in fewer fractures and deformities relative to severe cases. Cortical thickness is reduced in the shafts of the long bones, and accessory skull bones that are completely surrounded by cranial sutures (wormian bones) are present in the skull. Blue sclerae, thin skin, hyperextensibility of ligaments, otosclerosis with significant hearing loss, and hypoplastic and deformed teeth are characteristic of osteogenesis imperfecta. Cardiovascular and respiratory problems are the most common causes of morbidity and mortality in adulthood. Intelligence is not affected.

Affected patients are sometimes suspected of having suffered abuse. Osteogenesis imperfecta should be ruled out in any case of potential nonaccidental trauma. Of note, an olecranon fracture in a child is rare and can be indicative of osteogenesis imperfecta.

**Treatment**

Surgical treatment involves deformity correction of the long bones. Multiple intramedullary rods have been used to decrease the incidence of fractures and prevent deformity from fracture malunion. Patients are often confined to wheelchairs during adulthood. Bisphosphonates have been shown to decrease the incidence of fractures.

**Osteopetrosis (Osteitis Condensans Generalisata, Marble Bone Disease, Albers-Schönberg Disease)**

**Clinical Findings**

**A. Symptoms and Signs**

Osteopetrosis is a rare disorder of osteoclastic resorption of bone, resulting in abnormally dense bones. The reduced marrow spaces result in anemia. There are two types: a milder autosomal dominant type and a more malignant autosomal recessive type. The findings may appear at any age. Radiologic examination shows increased bone density and transverse bands in the shafts, clubbing of ends, and vertical striations of long bones. Thickening about the
cranial foramina is present, and heterotopic calcification of soft tissues is possible. Diminished life expectancy is seen in severe infantile forms.

**Treatment**

Treatment is largely symptomatic. The most severe autosomal recessive forms of osteopetrosis can be treated successfully by hematopoietic stem cell transplantation.

**Achondroplasia (Classic Chondrodystrophy)**

**Clinical Findings**

**A. Symptoms and Signs**

Achondroplasia is the most common form of short-limbed dwarfism. The upper arms and thighs are proportionately shorter than the forearms and legs. Skeletal dysplasia is suspected based on abnormal stature, disproportion, dysmorphism, or deformity. Measurement of height is an excellent clinical screening tool. Findings frequently include bowing of the extremities, a waddling gait, limitation of motion of major joints, relaxation of the ligaments, short stubby fingers of almost equal length, frontal bossing, midface hypoplasia, otolaryngeal system dysfunction, moderate hydrocephalus, depressed nasal bridge, and lumbar lordosis. Intelligence and sexual function are normal. While this disorder has an autosomal dominant transmission pattern, 80% of cases result from a random mutation in the fibroblast growth factor receptor-3 (FGFR3) gene.

**B. Imaging**

Radiographs demonstrate short, thick tubular bones and irregular epiphysial plates. The ends of the bones are thick, with broadening and cupping. Epiphyseal ossification may be delayed. Due to diminished growth in the spinal pedicles, the spinal canal is narrowed (congenital stenosis), and a herniated disk in adulthood may lead to acute paraplegia.

**Treatment**

Growth hormone is given to some children with bone dysplasia. Limb lengthening is possible to achieve a more normal proportion of extremities but is controversial.

**Osteochondrodystrophy (Morquio Disease)**

**Clinical Findings**

**A. Symptoms and Signs**

Morquio disease is an autosomal recessive disorder affecting mucopolysaccharide storage. Skeletal abnormalities include shortening of the spine, kyphosis, scoliosis, shortened extremities, pectus carinatum, genu valgum or "knock knees," and a hypoplastic odontoid with atlantoaxial instability. Appearance is generally normal at birth, with deformities developing between ages 1 and 4 years as a result of abnormal deposition of mucopolysaccharides. Increased urinary glycosaminoglycan levels are associated with increased severity.

**B. Imaging**

Radiographs demonstrate wedge-shaped flattened vertebrae and irregular, malformed epiphyses. The ribs are broad and have been likened to canoe paddles. The lower extremities are more severely involved than the upper extremities.

**Treatment**

The major treatment issue revolves around prevention of cervical myelopathy. Progressive hip subluxation, genu valgum, and ankle valgus often require surgical intervention. Bone marrow transplantation has been successful in alleviating some symptoms. Enzyme replacement therapy has emerged as another possible treatment option for afflicted patients. Prognosis depends on age of onset.

Orthopedic Aspects of Cerebral Palsy

Clinical Findings & Treatment

Cerebral palsy is defined as a nonprogressive brain injury causing muscle control issues that occurs while a child’s brain is developing. Early physical therapy encouraging completion of normal developmental patterns may benefit patients with cerebral palsy.

Bracing and splinting are of questionable benefit, although ankle and foot orthoses (AFOs) or night splints may be useful in preventing equinus deformity of the ankle, the most common deformity found in this population, or adduction contractures of the hips. Orthopedic surgery is useful for treating joint contractures that interfere with function. Muscle transfers are effective in carefully selected patients with cerebral palsy, and most orthopedic procedures are directed at tendon lengthening or bony stabilization by osteotomy or arthrodesis.

Flexion and adduction of the hip due to hyperactivity of the adductors and flexors may produce a progressive neuromuscular dislocation of the hip (Figure 26–13). This can lead to pain and dysfunction, with treatment being difficult and unsatisfactory. Treatment can include abduction bracing, supplemented by release of the adductors and hip flexors but this has been shown to only delay the need for osteotomy. Osteotomy of the femur and/or pelvis may be necessary to correct bony deformities of femoral anteversion, coxa valga, and acetabular dysplasia that are invariably present.

Surgeons must examine patients on several occasions before any operative procedure as it is difficult to predict the surgical outcome in individuals diagnosed with cerebral palsy. Follow-up care with a physical therapist can maximize the anticipated long-term gains and should be arranged before surgery.

Orthopedic Aspects of Myelodysplasia (Spina Bifida)

Clinical Findings & Treatment

Patients should be examined early by an orthopedic surgeon. The level of neurologic involvement determines the muscle imbalance that will be present to produce deformity with growth. The involvement is often asymmetrical and tends to change during the first 12–18 months of life. Associated musculoskeletal problems may include clubfoot, congenital dislocation of the hip, arthrogryposis-type changes of the lower extremities, and congenital scoliosis and kyphosis. Spina bifida lesions are most common at the L3–L4 level and tend to affect the hip joint, with progressive dislocation occurring during growth due to unopposed hip flexion and adduction forces. Foot deformities are complicated by the fact that sensation is generally absent; these deformities may be in any direction depending on the muscle imbalance present. Spinal deformities develop in a high percentage of these children, with scoliosis present in approximately 40%.

Ambulation may require long leg braces. In children who have a reasonable likelihood of walking, operative treatment consists of reduction of the hip, alignment of the feet in the weight-bearing position, as well as stabilization of the scoliosis. In children who lack active quadriceps function and extensor power of the knee, the likelihood of ambulation is greatly decreased. In such patients, aggressive surgery to the foot and hip region is usually not indicated as it may result in stiffening of the joints and prevent sitting. The overall treatment of the child with spina bifida should be coordinated in a multidisciplinary clinic where various medical specialists work with therapists, social workers, and teachers to provide the best possible care.

TRAVMA

ESSENTIALS OF DIAGNOSIS & TREATMENT

- Fall on outstretched hand (FOOSH) is most common mechanism.
- Directed physical examination (eg, swelling, tenderness, deformity, instability) and radiographic examination.
- Rule out physeal fracture.
- Early protected motion for sprains and strains.
- Reduction and immobilization for fractures.

Soft Tissue Trauma

A sprain is the stretching of a ligament and a strain is a stretch of a muscle or tendon. Contusions are generally due
to tissue compression, with damage to blood vessels within the tissue and the formation of a hematoma.

In a severe sprain, the ligament is completely disrupted resulting in instability of the joint. Incomplete tearing of the ligament, with local pain and swelling but no joint instability, is considered a mild or moderate sprain.

The initial treatment of any sprain consists of ice, compression, and elevation. Brief splinting followed by early range of motion exercises of the affected joint protect against further injury and relieves swelling and pain. Ibuprofen and other non-steroidal anti-inflammatory drugs are useful for pain. Rest, ice, and elevation are usually sufficient for mild or moderate sprains. If more severe trauma occurs, resulting in complete tearing of a ligament, instability of the joint may be demonstrated by gross examination or by stress testing with radiographic documentation. Such deformity of the joint may cause persistent instability resulting in other injuries. If instability is evident, surgical repair of the torn ligament may be indicated. If a muscle is torn at its tendinous insertion, it can be repaired surgically.

Ankle Sprains

Clinical Findings

A. Symptoms and Signs

The history will indicate that the injury was by either forceful inversion or eversion. The more common inversion injury results in tearing or injury to the lateral ligaments, whereas an inversion injury will injure the medial ligaments of the ankle. The injured ligaments can be identified by careful palpation for point tenderness around the ankle.

Treatment

The joint should be supported or immobilized in the functional position (right angle). Use of an air splint produces joint rest, and the extremity can be protected by using crutches. Functional rehabilitation to include edema control, range of motion, strengthening, and restoration of proprioceptive sensation can prevent long-term disability. Reinjury is common. Continued injury can lead to chronic ankle instability.

Knee Sprains

Clinical Findings

A. Symptoms and Signs

Sprains of the collateral and cruciate ligaments are uncommon in children. These ligaments are so strong that it is more common to have boney injury. In adolescence, rupture of the anterior cruciate ligament can result from a rotational injury.

Treatment

Effusion of the knee after trauma deserves referral to an orthopedic specialist. The differential diagnosis includes torn ligament, torn meniscus, and osteochondral fracture. If an injury produces avulsion of the tibial spine, associated injuries can include meniscal and chondral injuries, and anatomic reduction and fixation are often required. Non-traumatic effusion should be evaluated for inflammatory conditions (eg, juvenile rheumatoid arthritis) or patellar malalignment or instability.

Internal Derangements of the Knee

Clinical Findings

A. Symptoms and Signs

Meniscal injuries are uncommon in children younger than 12 years. Clicking or locking of the knee may occur in young children as a result of a discoid lateral meniscus, which is a rare congenital anomaly that has a higher risk of meniscal tear. As the child approaches adolescence, internal damage to the knee from a torsion weight-bearing injury may result in locking of the knee if tearing and displacement of a meniscus occurs. Osteochondritis dissecans, avascular necrosis of subchondral bone that can lead to cartilage cracking, instability and degeneration, also presents as swelling, pain, and mechanical symptoms of the knee in adolescence (Figure 26–14). This can be seen in all synovial joints, but the most common presentation is in the medial femoral condyle of the knee. Posttraumatic synovitis may mimic a meniscal lesion. Epiphysial injury should be suspected in any severe injury to the knee or when there is tenderness on both sides of the femoral metaphysis after injury. Stress films

▲ Figure 26–14. Bilateral medial femoral condyle osteochondritis dissecans.
will sometimes demonstrate separation of the distal femoral epiphysis.

**Back Sprains**

**Clinical Findings**

**A. Symptoms and Signs**

Sprains of the ligaments and muscles of the back are unusual in children but may occur as a result of violent trauma from automobile accidents or athletic injuries. Sprains usually cause lateral and midline pain over musculature. Back pain in a child may be the only symptom of significant disease and warrants clinical investigation. Inflammation, infection, renal disease, or tumors can cause back pain in children, and sprain should not be accepted as a routine diagnosis.

**Contusions**

**Clinical Findings**

**A. Symptoms and Signs**

Muscle contusions with hematoma formation produce the familiar “charley horse” injury.

**Treatment**

Treatment includes application of ice, compression, and rest. Exercise should be avoided for 5–7 days. Local heat may hasten healing once the acute phase of tenderness and swelling has passed.

**Myositis Ossificans**

**Clinical Findings**

**A. Symptoms and Signs**

Ossification within muscle occurs when sufficient trauma causes a hematoma that later heals in the manner of a fracture. Contusions of the quadriceps of the thigh or the triceps of the arm are the most common injuries. Disability is great, with local swelling, heat and extreme pain with the slightest provocation of the adjacent joint.

**Treatment**

The limb should be rested until the local reaction has subsided (5–7 days). When local heat and tenderness have decreased, gentle active exercises may be initiated. Passive stretching exercises are not indicated as they may stimulate the ossification reaction. If an extremity experiences a severe injury with a hematoma, it should be splinted and further activity should be avoided until the acute reaction has subsided. If additional trauma causes recurrent injury, ossification may reach spectacular proportions and resemble an osteosarcoma. Surgery to excise the ossification may restart the process and lead to an even more severe reaction and should not be attempted before 9 months to 1 year after injury.

**TRAUMATIC SUBLUXATIONS & DISLOCATIONS**

**Clinical Findings**

**Dislocation or Separation of the Shoulder**

**A. Symptoms and Signs and Treatment**

Shoulder dislocations usually following traumatic injury. Patients almost always present with shoulder pain, but can be with or without weakness or lack of function. The vast majority (~ 90%) of shoulder dislocations occur anteriorly and can have obvious deformity of the shoulder with anterior displacement of the humoral head. Posterior dislocation is rare. It is important to examine and evaluate both shoulders for any asymmetry between the two. Range of motion testing should be limited if a dislocation is suspected to limit further ligament and joint damage. Appropriate radiographic evaluation including anteroposterior, Grashey, and axillary views, is important for confirming a dislocation or separation diagnosis.

**Acromioclavicular (AC) separation**—AC separations involve partial or complete tearing of the ligament complex of the AC joint. They are among the most common shoulder injuries, but vary significantly in severity (grade I–VI, with the latter the most severe) and treatment. Grade I–III acromioclavicular separations are most common and generally treated nonsurgically (which includes early physical therapy), while grades IV–VI are usually the result of high energy impacts and are treated surgically. The amount of displacement distinguishes grade III from higher grades. There is controversy about whether grade III AC separations should be treated surgically or nonsurgically.

**Subluxation of the Radial Head** *(Nursemaid’s Elbow)*

**A. Symptoms and Signs and Treatment**

Infants may sustain subluxation of the radial head as a result of being lifted or pulled by the hand. The child appears with the elbow fully pronated and painful. The usual complaint is that the child’s elbow will not bend. Radiographic findings are normal, but there is point tenderness over the radial head. A subluxed radial head (nursemaid’s elbow) can be reduced by placing the elbow in full supination and slowly...
moving the arm from full extension to full flexion or by
holding the elbow at a 90-degree angle of flexion, then slowly
hyperpronating the wrist to complete reduction; a click may
be palpated at the level of the radial head. Relief of pain is
remarkable, as the child usually stops crying immediately.
The elbow may be immobilized in a sling for comfort for a
day. Occasionally, symptoms last for several days, requiring
more prolonged immobilization. A pulled elbow may be a
cue to battering. This should be considered during examina-
tion, especially if the problem is recurrent.

Oh LS: Effectiveness of reduction maneuvers in the treatment of
nursemaid’s elbow: A systematic review and meta-analysis. Am

Dislocation of the Patella
A. Symptoms and Signs

Complete patellar dislocations nearly always dislocate
laterally. Pain is severe, and the patient will present with
the knee slightly flexed and an obvious bony mass lateral to
the knee joint associated with a flat area over the anterior
knee. Radiologic examination confirms the diagnosis. When
subluxation of the patella occurs, symptoms may be more
subtle, and the patient will complain that the knee “gives
out” or “jumps out of place.”

Recurent dislocations more commonly occur in loose-
jointed individuals, especially adolescent girls. Factors that
affect risk for recurrence include length of patellar tendon,
the depth of trochlear groove, and position of the patella in
relation to the trochlear groove that is affected by axial and
coronal boney alignment.

Treatment of Dislocations

In contrast to fracture reduction, which may be safely post-
poned, dislocations must be reduced immediately in order to
minimize further joint damage. Dislocations can usually be
reduced by gentle sustained traction. Often, no anesthetic is
needed for several hours after the injury due to the protective
anesthesia produced by the injury. A thorough neurovascu-
lar examination should be performed and documented pre-
and post-reduction. Radiographs should be obtained
post-reduction to document congruency and assess for the
presence of associated osteochondral fractures. Following
reduction, the joint should be splinted for transportation
of the patient. Nonsteroidal anti-inflammatory drugs (NSAIDs)
may be used along with ice for pain control and to
reduce inflammation. The dislocated joint should be treated
by immobilization, followed by graduated active exercises
through a full range of motion. Vigorous passive manipula-
tion of the joint by a therapist may be harmful, but muscle
strengthening is the key in long-term treatment.

A dislocated patella can be reduced by extending the knee
and placing slight pressure on the patella while gentle tre-
tion is exerted on the leg. For first-time dislocation, initial
treatment after reduction should be nonoperative, consist-
ing of physical therapy to strengthen the quadriceps, hips,
and core stabilizers. Surgery is reserved for individuals with
reparable osteochondral injuries, loose bodies, and recur-
rent dislocation following appropriate nonoperative therapy.
Around one-third of patients report a repeated dislocation
after rehabilitation.

Surgical versus conservative management of acute patellar dislo-
Petri M et al: Operative vs conservative treatment of traumatic patel-
lar dislocation: results of a prospective randomized controlled
[PMID: 23138693].

Epiphyseal Separations

A. Symptoms and Signs

Epiphyseal separations (also referred to as epiphyseal fractures)
are more common than ligamentous injuries in children since
the ligaments of the joints are generally stronger than their asso-
ciated growth plates. Radiographs should be taken whenever a
dislocation is suspected in order to rule out epiphyseal fracture.
Radiographs of the opposite extremity, especially for injuries
around the elbow, are valuable for comparison. Fractures across
the growth plate may produce bony bridges that will cause
premature cessation of growth or angular deformities of the
extremity. These bridges are due to trauma to the growth plate
and can occur even with adequate reductions.

Treatment

Reduction of a fractured epiphysis should be done under anes-
thesia to align the growth plate with the least amount of force.
Epiphyseal fractures around the shoulder, wrist, and fingers
can usually be treated by closed reduction, but fractures of the
epiphyseal plates of the elbow often require open reduction.
In the lower extremity, accurate reduction of the epiphyseal plate
is necessary to prevent joint deformity when a joint surface is
involved. If angular deformities result, corrective osteotomy
may be necessary. Multiple attempts at closed reduction are not
recommended due to higher risk of physeal damage.

Torus Fractures

**Clinical Findings & Treatment**

Torus fractures consist of “buckling” of the cortex due to compression of the bone. They are most common in the distal radius or ulna. Alignment is usually satisfactory, and simple immobilization for 3 weeks is sufficient. Soft bandage therapy and cast therapy are effective in preventing further angulation. It is important that the fracture is not misdiagnosed as a greenstick fracture (see below) at initial presentation. Children with a torus fracture who are misdiagnosed with a greenstick fracture report having more pain after application of a soft bandage or cast.

Greenstick Fractures

**Clinical Findings & Treatment**

Greenstick fractures involve frank disruption of the cortex on one side of the bone but no discernible cleavage plane on the opposite side. The term “greenstick” implies similarity to what happens when one tries to break a twig/stick from a live tree; commonly bark will break on one side of the stick, while remaining intact on the opposite side. Bone ends are not separated, making these fractures angulated but not displaced. Reduction is achieved by straightening the arm into normal alignment and maintaining alignment with a snugly fitting cast. It is necessary to obtain radiographs of greenstick fractures again in 7–10 days to make certain that the reduction has been maintained in the cast. A slight angular deformity can be corrected by remodeling of the bone. The farther the fracture is from the growing end of the bone, the longer the time required for remodeling. The fracture can be considered healed when no tenderness is present and a bony callus is seen on a radiograph.

Fracture of the Clavicle

**Clinical Findings & Treatment**

Clavicular fractures are very common injuries in infants and children. The patient can be immobilized in a sling for comfort. The healing callus will be apparent when the fracture has consolidated, but this unsightly lump will generally resolve over a period of months to a year via bone remodeling. Operative fixation of clavicle fractures in children and adolescents is rarely indicated.

Supracondylar Fractures of the Humerus

**Clinical Findings**

**A. Symptoms and Signs**

The condyles of the distal humerus form the proximal half of the elbow joint. There is a concavity in the posterior distal humerus that is present anatomically to accommodate the olecranon when the elbow reaches full extension. This anatomic accommodation, located in what is referred to as the supracondylar region of the humerus, also creates a thinner area of cortical bone that is more susceptible to injury/fracture (Figure 26–15). Supracondylar fractures tend to occur in children age 3–6 years and are the most common elbow fracture in children. The proximity to the brachial artery in the distal arm creates a potential danger when dealing with these types of fractures. Absence of a distal pulse is a strong indicator of a secondary arterial injury. Swelling may be severe as these injuries are usually associated with a significant amount of trauma.

**Treatment**

Most often, these fractures are treated by closed reduction and percutaneous pinning performed under general anesthesia. Complications associated with supracondylar fractures include Volkmann ischemic contracture of the forearm due to vascular compromise and cubitus varus.
(decreased carrying angle, “gunstock deformity”) secondary to poor reduction. The “gunstock deformity” of the elbow may be somewhat unsightly but does not usually interfere with joint function.

General Comments on Other Fractures in Children

Reduction of fractures in children can usually be accomplished by simple traction and manipulation; open reduction is indicated if a satisfactory alignment is not obtained. Remodeling of the fracture callus generally produces an almost normal appearance of the bone over a matter of months. The younger the child, the more remodeling is possible. Angular deformities in the plane of joint motion remodel reliably while rotational malalignment does not remodel well.

There should be suspicion of child abuse whenever the age of a fracture does not match the history given or when the severity of the injury is more than the alleged accident would have produced. In suspected cases of battering in which no fracture is present on the initial radiograph, a repeat radiograph 10 days later is in order. Bleeding beneath the periosteum will be calcified by 7–10 days, and the radiographic appearance can be diagnostic of severe closed trauma characteristic of a battered child.

Clinical Findings

A. Symptoms and Signs

Osteomyelitis may be subtle in infants, presenting as irritability, diarrhea, or failure to feed properly; temperature may be normal or slightly low; and white blood cell count may be normal or only slightly elevated. There may be pseudoparalysis of the involved limb. Manifestations are more striking in older children, with severe local tenderness and pain and, often, but not invariably, high fever, rapid pulse, and elevated white blood cell count, ESR, and CRP. Osteomyelitis of a lower extremity often occurs around the knee joint in children age 7–10 years. Tenderness is most marked over the metaphysis of the bone where the process has its origin. For a child who refuses to bear weight, osteomyelitis is high in the differential diagnosis.

B. Laboratory Findings

Blood cultures are often positive early. The most important test is the aspiration of pus or biopsy of involved bone. It is useful to insert a needle into the bone in the area of suspected infection and aspirate any fluid present. Fluid should be stained for organisms and cultured. Even edema fluid can be useful for determining the causative organism. Elevation of the ESR above 50 mm/h is typical for osteomyelitis. CRP is elevated earlier than the ESR.
C. Imaging

Osteomyelitis should be diagnosed clinically before significant plain radiographic findings are present. Plain film findings progress from nonspecific local swelling, to elevation of the periosteum, with formation of new bone from the cambium layer of the periosteum occurring after 3–6 days. As infection becomes chronic, areas of cortical bone are isolated by pus spreading down the medullary canal, causing rarefaction and demineralization of the bone. Isolated pieces of cortex become ischemic and form sequestra (dead bone fragments). These radiographic findings are specific, but late. Bone scan is sensitive (before plain radiographic findings are apparent) but nonspecific and should be interpreted in the clinical context. MRI can demonstrate early edema and subperiosteal abscess and is helpful to confirm and localize disease prior to plain film changes.

Treatment

A. Specific Measures

Intravenous antibiotics should be started as soon as the diagnosis of osteomyelitis is made and diagnostic specimens have been obtained. Transition to oral antibiotics occurs when tenderness, fever, white cell count, and CRP are all resolved/decreasing and is facilitated by a positive culture. Agents that cover *S aureus* and *S pyogenes* (eg, oxacillin, nafcillin, cefazolin, and clindamycin) are appropriate for most cases of hematogenous osteomyelitis. Alternative antistaphylococcal therapy (eg, vancomycin) may be needed if methicillin-resistant and clindamycin-resistant *S aureus* is suspected or isolated. Methicillin-resistant *S aureus* infection should be suspected in patients with severe cases of hematogenous osteomyelitis. Coverage for other pathogens is also appropriate in specific circumstances (eg, group B *Streptococcus* in neonates and young infants, *Pseudomonas aeruginosa* for nail puncture-associated osteomyelitis, *Salmonella* species in children with sickle cell anemia). Surgical debridement and broader antibiotic coverage (guided by cultures of infected bone) are often indicated for osteomyelitis resulting from penetrating injury. Consultation with an infectious disease specialist is very helpful and standard in many facilities. For specific recommendations, see Chapter 42.

Acute osteomyelitis is usually treated for a minimum of 4–6 weeks and until normalization of the physical examination and inflammatory markers. Chronic infections are treated for months. Following surgical debridement, *Pseudomonas* foot infections usually respond to 1–2 weeks of antibiotic treatment.

B. General Measures

Splinting minimizes pain and decreases spread of the infection through lymphatic channels in the soft tissue. The splint should be removed periodically to allow active use of adjacent joints and prevent stiffening and muscle atrophy. In chronic osteomyelitis, splinting may be necessary to guard against fracture of the weakened bone.

C. Surgical Measures

Aspiration of the metaphysis for culture and Gram stain is the most useful diagnostic measure in any case of suspected osteomyelitis. If frank pus is aspirated from the bone, surgical drainage is indicated. If the infection has not shown a significant response within 24 hours, surgical drainage is also indicated. It is important that all devitalized soft tissue be removed and adequate exposure of the bone be obtained to permit free drainage. Excessive amounts of bone should not be removed when draining acute osteomyelitis as it will not be completely replaced by the normal healing process. Bone damage is limited by surgical drainage, whereas failure to evacuate pus in acute cases may lead to widespread damage.

Prognosis

When osteomyelitis is diagnosed in the early clinical stages and prompt antibiotic therapy is begun, the prognosis is excellent. If the process has been unattended for a week to 10 days, there is almost always some permanent loss of bone structure, as well as the possibility of future growth abnormality due to physeal injury.

Pyogenic Arthritis

The source of pyogenic arthritis varies according to the child’s age. Infantile pyogenic arthritis often develops from adjacent osteomyelitis. In older children, it presents as an isolated infection, usually without bony involvement. In teenagers with pyogenic arthritis, an underlying systemic disease or an organism that has an affinity for joints (eg, *Neisseria gonorrhoeae*) may be present.

The most frequent infecting organisms similarly vary with age: group B *Streptococcus* and *S aureus* in those younger than 4 months; *Haemophilus influenzae* B (if unimmunized) and *S aureus* in those aged 4 months to 4 years; and *S aureus* and *S pyogenes* in older children and adolescents. *Streptococcus pneumoniae* and *Neisseria meningitidis* are occasionally implicated, and *Neisseria gonorrhoeae* is a cause in adolescents. *H influenzae* B is now uncommon in the United States because of effective immunization. *Kingella kingae* is a gram-negative bacterium that is increasingly recognized as a cause of pyarthrosis (and, occasionally, osteomyelitis) in children younger than 5 years.
The initial effusion of the joint rapidly becomes purulent in pyogenic arthritis. A joint effusion may accompany osteomyelitis in the adjacent bone, but a white cell count exceeding 50,000/μL in the joint fluid indicates a purulent infection involving the joint. Generally, spread of infection is from bone into a joint, but unattended pyogenic arthritis may also affect adjacent bone. The ESR is often above 50 mm/h.

**Clinical Findings**

**A. Symptoms and Signs**

In older children, signs may be striking, with fever, malaise, vomiting, and restriction of motion, in addition to joint swelling, warmth, erythema, and/or tenderness. In infants, paralysis of the limb due to inflammatory pseudoparalysis may be evident. Infection of the hip joint in infants should be suspected if decreased abduction of the hip is present in an infant who is irritable or feeding poorly. A history of umbilical catheter treatment in the newborn nursery should alert the physician to the possibility of pyogenic arthritis of the hip.

**B. Imaging**

Early distention of the joint capsule is nonspecific and difficult to measure by plain radiograph. In infants with unrecognized pyogenic arthritis, dislocation of the joint may follow within a few days as a result of distention of the capsule by pus. Destruction of the joint space, resorption of epiphysial cartilage, and erosion of the adjacent bone of the metaphysis occur later. Bone scan shows increased flow and increased uptake about the joint. MRI and ultrasound imaging are useful adjuncts for detecting joint effusions, which can be helpful in assessing potential joint sepsis.

**Treatment**

Aspiration of the joint is the key to diagnosis. The need for aspiration is evaluated through the Kocher criteria that include fever, inability to bear weight, elevated WBC, ESR, and CRP. Surgical drainage followed by the appropriate antibiotic therapy provides the best treatment for pyogenic arthritis. Antibiotics can be selected based on the child’s age and results of the Gram stain and culture of aspirated pus. Reasonable empiric therapy in infants and young children is nafcillin or oxacillin plus a third-generation cephalosporin. An antistaphylococcal agent alone is usually adequate for children older than 5 years, unless gonococcal or meningococcal infection is suspected. Alternative antistaphylococcal therapy (eg, clindamycin or vancomycin) may be needed if methicillin-resistant *S aureus* is suspected or isolated. Consultation with an infectious disease specialist can be helpful.

For staphylococcal infections, a minimum of 3 weeks of therapy and until examination and inflammatory markers are normal is recommended; for other organisms, a minimum of 2 weeks and until examination and inflammatory markers are normal is usually sufficient. Oral therapy may be begun when clinical signs and inflammatory markers have improved markedly. It is not necessary to give intra-articular antibiotics since good levels are achieved in the synovial fluid with parenteral administration.

**Prognosis**

The prognosis for the patient with pyogenic arthritis is excellent if the joint is drained before damage to the articular cartilage has occurred. If infection is present for more than 24 hours, dissolution of the proteoglycans in the articular cartilage takes place, with subsequent arthrosis and fibrosis of the joint. Damage to the growth plate may occur, especially within the hip joint, where the epiphysal plate is intracapsular.

---

**Diskitis**

Diskitis is pyogenic infectious spondylitis in children. Although many infections are culture-negative, *S aureus* is considered to be the most frequent etiologic pathogen. The typical clinical presentation includes back pain and malaise over a several weeks to months duration. Younger children, less than 5 years, may not be able to localize their complaints and commonly present with “abdominal” pain. Supportive treatment and appropriate antibiotics are likely to lead to rapid relief of symptoms and signs without recurrence.

**Transient (Toxic) Synovitis (Versus Septic Arthritis of the Hip)**

**Clinical Findings**

**A. Symptoms and Signs**

The most common cause of limping and hip pain in children in the United States is transient synovitis. This acute inflammatory reaction often follows an upper respiratory or gastrointestinal infection and is generally self-limited. Classically affecting children aged 3–10 years, it is more common in boys than girls. The hip joint experiences limitation of motion, particularly internal rotation, and radiographic
changes are nonspecific, with some swelling apparent in the soft tissues around the joint.

It is important for the provider to differentiate between transient synovitis and septic arthritis upon initial presentation. Early in the disease both conditions have similar symptoms but each requires a different treatment plan. Generally, toxic synovitis of the hip is not associated with elevation of the ESR, white blood cell count, or temperature above 38.3°C. In questionable cases, aspiration of the hip yields only yellowish fluid in transient synovitis rather than purulent fluid in pyogenic arthritis. Transient synovitis can be distinguished from septic arthritis with a dynamic contrast enhanced MRI (DCE-MRI).

**Treatment**

Rest and nonsteroidal anti-inflammatory medications are the preferred treatments for transient synovitis, whereas patients afflicted with septic arthritis of the hip are treated with operative drainage followed by antibiotic treatment. NSAIDs shorten the course of the transient synovitis, although even with no treatment, the disease usually runs its course in days. Radiographic follow-up is essential as toxic synovitis may be the precursor of avascular necrosis of the femoral head (described in the next section) in a small percentage of patients. Radiographs can be obtained at 6 weeks, or earlier if either a persistent limp or pain is present.

---

**VASCULAR LESIONS & AVASCULAR NECROSIS (OSTEOCHONDROSES)**

**ESSENTIALS OF DIAGNOSIS & TREATMENT**

- Diagnosis made by characteristic radiographic findings.
- Radiographic resolution lags behind symptomatic resolution.
- Treatment for most cases is supportive.

Osteochondrosis (degeneration of an ossification center) due to vascular lesions may affect various growth centers. Table 26–1 indicates the common sites and the typical ages at presentation.

In contrast to other body tissues that undergo infarction, bone removes necrotic tissue and replaces it with living bone through creeping substitution (a process where necrotic bone is replaced by viable bone). This replacement of necrotic bone may be so complete that a normal bone results. Adequacy of replacement depends on the patient's age, the presence or absence of associated infection, the congruity of the involved joint, and other physiologic and mechanical factors.

Rapid growth of the secondary ossification centers in the epiphyses in relation to their blood supply subject them to avascular necrosis. Despite the number of different names referring to avascular necrosis of the epiphyses (see Table 26–1), the process is identical: necrosis of bone followed by replacement.

Even though the pathologic and radiographic features of avascular necrosis of the epiphyses are well known, the cause is not generally agreed upon. Necrosis may follow known causes such as trauma or infection, but idiopathic lesions usually develop during periods of rapid growth of the epiphyses.

**Table 26–1. The osteochondroses.**

**Avascular Necrosis of the Proximal Femur (Legg-Calvé-Perthes Disease)**

**Clinical Findings**

**A. Symptoms and Signs**

The highest incidence of Legg-Calvé-Perthes disease occurs between 4 and 8 years of age and occurs when the vascular supply to the proximal femur is interrupted. Persistent pain is the most common symptom, and the patient may present with limp or limitation of motion.

**B. Imaging**

Radiographic findings correlate with progression of the disease and the extent of necrosis. Effusion of the joint associated with slight widening of the joint space and periarticular swelling are the early findings. Decreased bone density in
and around the joint is apparent after a few weeks. The necrotic ossification center appears denser than the surrounding viable structures, and the femoral head is collapsed or narrowed. As replacement of the necrotic ossification center occurs, rarefaction of the bone begins in a patchwork fashion, producing alternating areas of rarefaction and relative density, referred to as "fragmentation" of the epiphysis. Widening of the femoral head may be associated with flattening, or coxa plana. If infarction has extended across the growth plate, a radiolucent lesion will be evident within the metaphysis. If the growth center of the femoral head has been damaged and normal growth arrested, shortening of the femoral neck results. Eventually, complete replacement of the epiphysis develops as living bone replaces necrotic bone by creeping substitution. The final shape of the head depends on the extent of the necrosis and collapse of weakened bone. Serial radiographs help to distinguish this disease from transient synovitis of the hip.

Treatment
Protection of the joint by minimizing impact is the principal treatment. If the joint is deeply seated within the acetabulum and normal joint motion is maintained, a reasonably good hip can result. Little benefit has been shown from bracing. Surgical treatment is controversial.

Prognosis
The prognosis for complete replacement of the necrotic femoral head in a child is excellent, but the functional result depends on the amount of deformity that has developed. Better outcomes are observed for patients with an onset of symptoms before the age of 6. Generally a poorer prognosis is expected for patients who develop the disease late in childhood, those with more completed involvement of the epiphysial center, those with metaphysial defects and those who have more complete involvement of the femoral head.

Osteochondritis Dissecans
Clinical Findings
A. Symptoms and Signs
In osteochondritis dissecans, a wedge-shaped necrotic area of subchondral bone can lead to significant chondral damage. The fragment of bone may break off from the host bone and displace into the joint as a loose body. If it remains attached, the necrotic fragment may be completely replaced through creeping substitution. The pathologic process is the same as that for avascular necrosing lesions of ossification centers. Joint damage may occur because of the proximity of these lesions to adjacent articular cartilage.

The knee (medial femoral condyle, Figure 26–14), the elbow joint (capitellum), and the talus (superior lateral dome) are the most common sites for these lesions. Joint pain is the usual presenting complaint; however, local swelling or locking may be present, particularly if a fragment is free in the joint. Laboratory studies are normal.

Treatment
Treatment consists of protection of the involved area from mechanical damage. Stable/attached lesions are generally treated with activity modification and immobilization for 3–6 months. Unstable/dislodged lesions are treated surgically with arthroscopic drilling, in order to bring new blood flow to the area, and fixation to stabilize the lesion. For some marginal lesions, it may be worthwhile to drill the necrotic fragment to encourage more rapid vascular in-growth and replacement. If a fragment is free within the joint as a loose body, it must be removed. If large areas of a weight-bearing joint are involved, secondary degenerative arthritis may result. Adolescents have less favorable outcomes with non-operative therapy.

NEOPLASIA OF THE MUSCULOSKELETAL SYSTEM

ESSENTIALS OF DIAGNOSIS & TREATMENT

Most typically present with unresolving pain.
Reassess any child with unresolved pain previously thought benign in origin.
Obtain radiographs.
Refer any suspicious lesions for specialty evaluation.

The poor prognosis of malignant tumors arising in the bone or other tissues derived from the mesoderm makes neoplastic diseases of the musculoskeletal system a serious problem. Fortunately, few benign lesions undergo
malignant transformation. Accurate diagnosis depends on correlation of the clinical, radiographic, and microscopic findings. Complaints about the knee should be investigated for tumor, although the usual causes of knee pain are traumatic, infectious, or developmental in origin.

Osteochondroma

► Clinical Findings

A. Symptoms and Signs

Osteochondroma is the most common benign bone tumor in children. It usually presents as a pain-free mass. When present, pain is caused by bursitis or tendinitis due to irritation by the tumor. Lesions may be single or multiple. Pathologically, the lesion is a bone mass capped with cartilage. These masses result from a developmental defect of the growth plate and tend to grow during childhood and adolescence in proportion to the child’s growth. Males are more affected than females. Generally, the tumors are present on radiographs in the metaphyseal region of long bones and may be pedunculated or sessile. The cortex of the underlying bone “flows” into the base of the tumor.

► Treatment

An osteochondroma should be excised if it interferes with function, is frequently traumatized, or is large enough to be deforming. The prognosis is excellent. Malignant transformation is very rare.

Osteoid Osteoma

► Clinical Findings

A. Symptoms and Signs

Osteoid osteoma is a benign bone-forming lesion of unclear etiology.

It classically produces night pain that can be relieved by nonsteroidal anti-inflammatory drugs. On physical examination, there usually is tenderness over the lesion. An osteoid osteoma in the upper femur may cause referred pain to the knee.

The radiographic lesion consists of a radiolucent nidus surrounded by dense osteosclerosis that may obscure the nidus. Bone scan shows intense uptake in the lesion. CT scans are confirmatory and delineate the nidus well.

► Treatment

Surgical excision or radiofrequency ablation of the nidus is curative and may be done using computed tomography imaging and a minimally invasive technique. The prognosis is excellent, with no known cases of malignant transformation, although the lesion has a tendency to recur if incompletely excised.

Chondroblastoma

► Clinical Findings & Treatment

The presenting complaint in chondroblastoma (benign chondral origin lesions typically in the epiphyses [joint ends] of long bones) is pain around a joint. This neoplasm may produce a pathologic fracture. On radiograph, the lesion is radiolucent and usually located in the epiphysis. With little to no reactive bone, calcification is unusual. The lesion is treated by surgical curettage and bone grafting. The prognosis is excellent if complete curettage is performed. There is no known malignant transformation.

Nonossifying Fibroma

► Clinical Findings & Treatment

Nonossifying fibroma, or benign cortical defect, is nearly always an incidental finding on radiograph. Nonossifying fibroma is a radiolucent lesion eccentrically located in the metaphyseal region of the bone. Usually a thin sclerotic border is evident. Multiple lesions may be present. The most frequent sites are the distal femur and proximal tibia. In general, no treatment is needed because these lesions heal as they ossify with maturation and growth. Rarely, pathologic fractures result from large lesions.
Osteosarcoma

Clinical Findings

A. Symptoms and Signs

Osteosarcoma is an aggressive form of cancer characterized by chromosomal instability. It is suspected that microRNAs (noncoding, single-stranded molecules of RNA that regulate gene expression) play an important role in cancer development. The presenting complaint is usually pain in a long bone; however, the patient may present with, loss of function, mass, or limp. Pathological fracture is uncommon. The malignant osseous tumor produces a destructive, expanding, and invasive lesion. A triangle may be adjacent to the tumor, produced by elevated periosteum and subsequent tumor ossification. The lesion may contain calcification and violates the cortex of the bone. Femur, tibia, humerus, and other long bones are the sites usually affected.

Treatment

Surgical excision (limb salvage) or amputation is indicated based on the extent of the tumor. Adjuvant chemotherapy is routinely used prior to surgical excision. The prognosis is improving, with 60%–70% long-term survival rates reported in modern series. Death usually occurs as a result of lung metastasis. Patients with osteosarcoma complicated by pathological fracture have lower long-term survival rates than patients with osteosarcoma and no pathological fracture.

Ewing Sarcoma

Clinical Findings

A. Symptoms and Signs

In Ewing sarcoma, the presenting complaint is usually pain and tenderness, but fever and leukocytosis may be present. Osteomyelitis is the main differential diagnosis. The lesion may be multicentric. Ewing sarcoma is radiolucent and destroys the cortex, frequently in the diaphyseal region. Reactive bone formation may occur about the lesion, seen as successive layers of the so-called onion skin layering.

Treatment

Treatment is with multiagent chemotherapy, radiation, and surgical resection. Large tumor size, pelvic lesions, and inadequate response to chemotherapy portend a poor prognosis.

Fibrous Dysplasia

Dysplastic fibrous tissue replacement of the medullary canal is accompanied by the formation of metaplastic bone in areas with fibrous dysplasia. Three forms of the disease are recognized: monostotic, polyostotic, and polyostotic with endocrine disturbances (precocious puberty in females, hyperthyroidism, and hyperadrenalism [Albright syndrome]).

Clinical Findings

A. Symptoms and Signs

The lesion or lesions may be asymptomatic. If present, pain is probably due to pathologic fractures (Figure 26–16). In females, endocrine disturbances may be present in the polyostotic variety and are associated with café au lait spots.

B. Imaging

The lesion begins centrally within the medullary canal, usually of a long bone, and expands slowly. Pathologic fracture
may occur. If metaplastic bone predominates, the contents of the lesion have the density of bone. The disease is often asymmetrical, and limb length disturbances may occur as a result of stimulation of epiphysial cartilage growth. Marked deformity of the bone may result, and a shepherd’s crook deformity of the upper femur is a classic feature of the disease.

**Treatment**

If the lesion is small and asymptomatic, no treatment is needed. If the lesion is large and produces or threatens pathologic fracture, curettage and bone grafting are indicated. The prognosis is good, as malignant transformation is rare.

**BONE CYSTS, BAKER CYST, & GANGLIIONS**

**Clinical Findings**

**A. Symptoms and Signs**

**Unicameral Bone Cyst**

Unicameral bone cysts occur in the metaphysis of a long bone, usually in the femur or humerus. A cyst begins in the medullary canal adjacent to the epiphysial cartilage. It probably results from some fault in enchondral ossification (the process where bone is formed from cartilaginous precursors). The cyst is considered active as long as it abuts onto the metaphysial side of the epiphysial cartilage, and there is a risk of growth arrest with or without treatment. When a border of normal bone exists between the cyst and the epiphysial cartilage, the cyst is inactive. The lesion is usually identified when a pathologic fracture occurs, producing pain. Laboratory findings are normal. On radiograph, the cyst is identified centrally within the medullary canal, producing expansion of the cortex and thinning over the widest portion of the cyst.

**Aneurysmal Bone Cyst**

Aneurysmal bone cyst is similar to unicameral bone cyst, except it contains blood rather than clear fluid. It usually occurs in a slightly eccentric position in a long bone, expanding the cortex of the bone but not breaking the cortex. Involvement of the flat bones of the pelvis is less common.

On radiographs, the lesion appears somewhat larger than the width of the epiphysial cartilage, distinguishing it from a unicameral bone cyst.

Chromosomal abnormalities have been associated with aneurysmal bone cysts. The lesion may appear aggressive histologically, and it is important to differentiate it from osteosarcoma or hemangioma.

**Baker Cyst**

A Baker cyst is a herniation of the synovium in the knee joint into the popliteal region. In children, the diagnosis may be made by aspiration of mucinous fluid, but the cyst nearly always disappears with time.

**Ganglion**

A ganglion is a smooth, small cystic mass connected by a pedicle to the joint capsule, usually on the dorsum of the wrist. It may also occur in the tendon sheath over the flexor or extensor surfaces of the fingers. Ganglia may interfere with function or cause persistent pain.

**Treatment**

Treatment of bone cysts and ganglion can be by curettage and bone grafting. Baker cysts usually require no surgical treatment. Ganglia can be excised if they cause symptoms.

**QUALITY ASSURANCE/IMPROVEMENT INITIATIVES IN ORTHOPEDICS**

The Pediatric Orthopedic Society of North America (POSNA) has an ongoing, well-developed quality, safety, and value initiative (QSVI). QSVI research is included during the POSNA annual scientific meeting.

Sports medicine as a separate discipline has grown since the 1980s in response to an expanding body of knowledge in the areas of exercise physiology, biomechanics, and musculoskeletal medicine. As more children participate in recreational and competitive activities, pediatric health care providers are encountering more young athletes in their practice. Familiarity with the common medical and orthopedic issues faced by athletically active children and knowledge of which injuries necessitate referral to a sports medicine specialist are essential.

**BASIC PRINCIPLES**

**Pediatric Injury Patterns**

Although young athletes have injuries and issues similar to those of adults, there are many injuries that are unique to the pediatric and adolescent athlete. An understanding of the differences between adult and pediatric injury patterns is important to foster an appropriate index of suspicion for situations unique to pediatrics.

Components of a long bone include the diaphysis, metaphysis, and epiphysis. In the pediatric bone architecture, the presence of cartilaginous growth plates and apophyses predispose children to unique injury patterns that are different from their adult counterparts. Open growth plates or physes and their various stages of development are important factors to consider when treating young athletes. The physes are located at the ends of the long bones and are the primary ossification centers where length is added to the immature skeleton. The physis is a weak link in the musculoskeletal complex and has a high risk of fracture during periods of rapid growth. The surrounding soft tissues, including ligaments and tendons, are relatively stronger than the physis. The epiphyses are secondary centers of ossification that also contribute to long bone formation and, like the adjacent articular cartilages, are vulnerable to trauma. Injuries that involve the epiphysis can lead to joint deformity. The apophyses are secondary centers of ossification that add contour but not length to the bone. The apophysis is the attachment site of the muscle-tendon unit and is vulnerable to both acute and chronic overuse traction injury during times of rapid growth. Unlike injuries to the physis and epiphysis, however, apophyseal injuries do not result in long-term growth disturbance. Recognizing injuries to growth centers is important because of the risk for partial or complete physeal arrest. Complications of growth plate injury can lead to limb length discrepancy or angular deformity.

**FITNESS & CONDITIONING**

Compared to children who are sedentary, physically active youth tend to develop greater agility and skills and maintain better fitness throughout their lifetime. Young children and adolescents should participate in physical activity for 60 minutes or more each day. To improve overall fitness and reduce the risk of injury, children and adolescents should focus on three different components of exercise:

1. **Integrative training** (curriculum of diverse skills, increasing fitness, and appropriate rest periods). Examples include developing fundamental skills and technique, learning proper movement mechanics, aerobic and anaerobic conditioning.
2. **Neuromuscular conditioning** (mixture of basic fundamental and specialized motor control exercises aimed at improving general health and sports performance). Examples include core strength exercises, agility, and plyometrics.
3. **Resistance** (strength) training (progressive resistive loads in a variety of modalities).
Periodization is a training concept that emphasizes variations in the volume and intensity of training throughout the year in a conditioning program. Continuously varying the specific type and goals of training provides adequate recovery from each strenuous exercise session and avoids overtraining, burnout, and overuse injuries.

**Strength Training**

*Strength* is defined as the peak force that can be generated during a single maximal contraction. Strength training uses progressive resistance to improve an athlete’s ability to resist or exert force. This can be achieved by a variety of techniques, including body weight, free weight, or machine resistance. The benefits of strength training include improved performance, endurance, and muscular strength. Strength training can be safely started in prepubescent athletes as early as 7 and 8 years old if designed appropriately with a focus on lighter resistance, increased repetitions, proper technique and mechanics, coordination, and building self-confidence. During preadolescence, it is thought that strength training leads to increased strength largely through improved neuromuscular adaptation as opposed to muscular hypertrophy. As such, attempts to gain fat-free mass through maximal weight lifting and high weight, low repetition resistance training regimens may not have that desired effect. Children mature at varying paces, and strength training programs should be individualized to accommodate for these unique differences. All strength training regimens should be modified as needed to remain age-appropriate and pain-free. Tanner staging (see Chapter 34) helps define readiness for progression to more strenuous programs. Power lifting and maximal weight lifting should be restricted to athletes who have reached or passed Tanner stage V. To prevent injuries, care should be taken to instruct children on the proper use of weight-training equipment at home. Children and adults with disabilities can benefit from weight-training programs modified to meet their specific needs.

**SPORTS NUTRITION**

Proper nutrition in young athletes focuses on maintaining an appropriate energy balance; creating healthy eating and hydration habits; and avoiding harmful food, drink, and supplement choices. Keeping an adequate nutritional intake will increase lean muscle mass, maximizing strength, endurance, immunity, and training benefit. Athletes should be encouraged to balance caloric intake with energy expenditure, eat whole grains, avoid processed foods, focus on healthy fats and proteins, and maintain proper hydration. Carbohydrates should compose 50%–60% of a young athlete’s diet, with fat and protein making up 25%–30% and 15%–25%, respectively. Hydration can come mainly from water if the exercise lasts less than 1 hour, after which time a carbohydrate-containing sports drink is appropriate. Water or sports drinks should be consumed every 15–20 minutes during prolonged exercise greater than 1 hour or in hot playing conditions. For bouts of exercise lasting greater than 1 hour, some carbohydrates should be ingested as well. These carbohydrates can be in the liquid form as sports drinks or solids combined with water. A light snack and hydration are recommended prior to and immediately after an extended workout. To avoid excessive caloric and sugar intake, sports drinks are not recommended at meals or times other than prolonged exercise. The average athlete eats a well-balanced diet not necessitating nutritional supplementation. However, if food allergies or improper dietary intake is confirmed, an athlete may benefit from a daily multivitamin. In general, nutritional sports supplements are not recommended and extreme caution is suggested when considering their use. The supplement industry is not well regulated and contamination with toxic and banned substances has been noted in the past. Similarly, energy drinks are not recommended for use in any youth younger than 18 years due to high levels of caffeine and other stimulants contained in such beverages.

**PREPARTICIPATION PHYSICAL EVALUATION**

The ultimate goal of the preparticipation physical evaluation (PPE) is to promote the health and safety of athletes. Its primary objectives are to screen for conditions that may be life threatening or disabling and for conditions that may predispose to injury or illness. Secondary objectives of the PPE include establishing a medical home, determining the general health of the individual, assessing fitness for
specific sports, and counseling on injury prevention and health-related issues. The ideal timing of the examination is at least 6–8 weeks before training starts. This allows time to further evaluate, treat, or rehabilitate any identified problems.

**Preparticipation History**

The medical history is the most important part of the encounter, identifying 65%–77% of medical and musculoskeletal conditions. Therefore, obtaining a thorough and accurate history is essential in identifying conditions that may affect a child’s ability to safely participate in sports. Many key elements should be explored with the athlete. A standardized PPE form, endorsed by six medical societies, including the American Academy of Pediatrics (AAP), is available in the fourth edition of the PPE monograph (Bernhard and Roberts 2010) or on the Internet (https://www.aap.org/en-us/about-the-aap/Committees-Councils-Sections/Council-on-sports-medicine-and-fitness/Pages/PPE.aspx). This monograph, formulated based on current literature, policies, consensus statements, expert opinion, and extensive peer review, is currently the recommended standard for the preparticipation physical examination in the United States. The history includes the following areas:

**A. Cardiovascular History**

The routine use of electrocardiogram (ECG) and echocardiography in the preparticipation cardiovascular screening in athletes remains a highly debated topic in sports medicine and sports cardiology. Despite ongoing controversy, the American Heart Association (AHA) currently recommends against its routine usage in asymptomatic athletes because of its low sensitivity, high false-positive rate, limited resources, lack of trained physicians to interpret the ECG, and poor cost-effectiveness due to the low prevalence of disease. In 2007, the AHA updated its consensus statement on cardiovascular screening stating its position to this effect. According to the AHA, the goal of the PPE is to reduce cardiovascular risk associated with physical activity. The 2007 AHA recommendations for cardiovascular screening are incorporated in the fourth edition PPE monograph and include the following 12-point screen:

**Personal Medical History:**

1. Chest pain or discomfort with exercise
2. Syncope or near syncope associated with exercise
3. Excessive shortness or breath or fatigue associated with exertion
4. History of heart murmur
5. History of elevated blood pressure

Family Medical History:
6. Premature death before age 50 years due to heart disease
7. Disability from heart disease in a close relative younger than 50 years
8. Knowledge of specific cardiac conditions: hypertrophic or dilated cardiomyopathy, long QT syndrome, other ion channelopathies, Marfan syndrome, or arrhythmias

**Physical Examination:**

9. Auscultation of heart murmur in supine and standing position
10. Palpation of radial and femoral pulses
11. Physical stigmata of Marfan syndrome
12. Brachial blood pressure taken in seated position

Sudden cardiac arrest is the leading medical cause of sudden death in young athletes. Addressing these areas may help identify potentially life-threatening cardiac lesions. However, clinicians should keep in mind that there are currently no outcome-based studies that demonstrate the effectiveness of the PPE in preventing sudden cardiac death in athletes. In the United States, the most common causes of sudden cardiac death on the playing field are hypertrophic cardiomyopathy (HCM) and congenital coronary artery anomalies, with HCM accounting for one-third of sudden cardiac deaths in young athletes. Any athletes with cardiovascular symptoms require further evaluation before allowing them to participate in sports. Any activity restrictions or sports disqualification for an athlete should be made in consultation with a cardiologist.

**B. History of Hypertension**

Any history of hypertension requires investigation for secondary causes of hypertension and target organ disease. An athlete with hypertension who exercises may cause their blood pressure to rise even higher, placing them at increased risk for complications. Athletes should also be asked about the use of stimulants (ie, caffeine, nicotine, attention deficit disorder medications) and a family history of hypertension. The diagnosis of hypertension in children younger than 18 years is based on gender, age, and height, and the blood pressure must be measured on three separate occasions. Blood pressure measurements with values from 90% to 95% of gender, age, and height-based norms are considered prehypertension; values from 95% to 5 mm Hg above the 99% of norms are defined as stage 1 hypertension; and values greater than 5 mm Hg above the 99% of norms are defined as stage 2 hypertension.

Athletes with prehypertension are eligible to participate in sports. Counseling regarding lifestyle modifications should be made, including healthy dietary changes, weight management, and daily physical activity. Those with stage
1 hypertension, in the absence of end-organ damage, may also participate in competitive sports but with appropriate subspecialist referral if the individual is symptomatic, have associated heart disease or structural abnormality, or have persistent elevated blood pressure on two additional occasions despite lifestyle modifications. Athletes who have stage 2 hypertension or end-organ damage should not be cleared to participate in competitive sports until their blood pressure is evaluated, treated, and is under control.

C. Central Nervous System

A history of frequent or exertional headaches, seizure disorders, concussions or head injuries, recurrent stingers or burners, or cervical cord neuropraxia may affect an athlete’s ability to participate in sports. These conditions require further evaluation, rehabilitation, or informed decision making prior to clearance for sports participation. The fourth edition PPE monograph provides an updated review and recommendations on concussions in sports. (See also section Concussion.)

D. History of Chronic Diseases

Diseases such as reactive airway disease, exercise-induced asthma, diabetes, renal disease, liver disease, chronic infections, or hematologic diseases should be noted.

E. Surgical History

Surgical history may influence participation in certain sports. Full recovery with no long-term impact on athletic performance is required prior to clearance.

F. Infectious Mononucleosis

Ask about infectious mononucleosis in the last 4 weeks. The risk for splenic rupture is highest within the first 3 weeks of illness and can occur in the absence of trauma. Therefore, physical activity should be avoided during the first 3–4 weeks after the infection starts. The athlete may return to play once clinical symptoms are resolved and risk for splenic rupture is assessed as minimal. The use of serial abdominal ultrasound to assess spleen size to aid in return to play decisions is likely not useful nor recommended. Parameters for spleen size based on ethnicity, sex, height, and weight have not yet been established, so determining when spleen size has normalized based on imaging becomes difficult.

G. Musculoskeletal Limitations and Prior Injuries

The physician should inquire about joints with limited range of motion, muscle weakness, and prior injuries that may affect future performance. Chronic pain or soreness long after activity may reflect overuse syndromes that should be evaluated.

H. Menstrual History in Females

The physician should pay particular attention to the so-called female athlete triad: amenorrhea disordered eating and osteoporosis.

I. Nutritional Issues

The physician should record methods the athlete uses to maintain, gain, or lose weight. Eating disorders or inadequate nutritional intake could lead to persistent or recurrent injury, including stress fractures. Vitamin D deficiency has become increasingly common in female athletes due to inadequate dietary intake or decreased sunlight exposure.

J. Medication History

Inquire about the use of prescription medications, over-the-counter medications, and supplements. Not only will medications reveal problems omitted in the medical history, but the information will also provide data on current medications whose side effects may suggest activity modifications. Documenting drug use may provide the opportunity to explore with the patient the drawbacks of performance-enhancing compounds such as anabolic steroids, creatine, stimulants, and narcotics.

Physical Examination

The physical examination should be focused on the needs of the athlete. It may be the only time an athlete has contact with medical personnel and can be used to promote wellness along with screening for physical activity. An example of a preparticipation physical examination form is endorsed in the fourth edition of the PPE monograph (Bernhardt and Roberts 2010) and is available at https://www.aap.org/en-us/about-the-aap/Committees-Councils-Sections/Council-on-sports-medicine-and-fitness/Pages/PPE.aspx. The examination should include routine vital signs, including blood pressure measurements obtained in the upper extremity. The cardiovascular examination should include palpation of pulses, auscultation for murmurs while sitting and standing, evaluation for physical stigmata of Marfan syndrome, and assessment of any cardiovascular symptoms as previously described. The musculoskeletal examination is used to determine strength, range of motion, flexibility, and previous injuries. Included is a quick guide that can be used to screen for musculoskeletal abnormalities (Table 27–1). The remainder of the examination should emphasize the following areas:

A. Skin

Are there any contagious lesions such as herpes or impetigo?
**B. Vision**
Are there any visual problems? Is there any evidence of retinal problems? Are both eyes intact?

**C. Abdomen**
Is there any evidence of hepatosplenomegaly?

**D. Genitourinary System**
Are any testicular abnormalities or hernias present?

**E. Neurologic System**
Are there any problems with coordination, gait, or mental processing?

**F. Sexual Maturity**
What is the individual’s Tanner stage?

**Recommendations for Participation**
After completing the medical evaluation, the physician can make recommendations about sports clearance. The options include the following:
- Cleared for all sports without restrictions
- Cleared for all sports without restrictions with recommendations for further evaluation or treatment
- Not cleared: pending further evaluation, for any sports, or for certain sports

Table 27–2 is a composite of recommendations for sports participation organized by body system. Recommendations

---

<table>
<thead>
<tr>
<th>Evaluation Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>General evaluation</td>
<td>Have patient stand in front of examiner; evaluate both front and back along with posture. Look at general body habitus. Look for asymmetry in muscle bulk, scars, or unusual postures. Watch how patient moves when instructed.</td>
</tr>
<tr>
<td>Neck evaluation</td>
<td>Evaluate ROM by having patient bend head forward (chin to chest), rotate from side to side and laterally bend (ear to shoulder). Observe for asymmetry, lack of motion, or pain with movement.</td>
</tr>
<tr>
<td>Shoulder and upper extremity evaluation</td>
<td>Observe clavicles, shoulder position, scapular position, elbow position, and fingers. ROM screening: Fully abduct arms with palms in jumping jack position. Internally and externally rotate shoulder. Flex and extend wrist, pronate and supinate wrist, flex and extend fingers. Do the following manual muscle testing: Have patient shrug shoulders (testing trapezius). Abduct to 90 degrees (testing deltoid). Flex elbow (testing biceps). Extend elbow over head (testing triceps). Test wrist flexion and extension. Have patient grasp fingers.</td>
</tr>
<tr>
<td>Back evaluation</td>
<td>General inspection to look for scoliosis or kyphosis. ROM screening: Bend forward touching toes with knees straight (spine flexion and hamstring range). Rotation, side bending, and spine extension.</td>
</tr>
<tr>
<td>Gait and lower extremity evaluation</td>
<td>General observation while walking. Have patient walk short distance normally (look at symmetry, heel-toe gait pattern, look at all joints involved in gait and leg lengths, any evidence of joint effusions or pain). Have patient toe-walk and heel-walk for short distance and check tandem walking (balance beam walking).</td>
</tr>

<tr>
<td>Diabetes mellitus type 1</td>
<td>No restrictions to activity. However, athletes are at risk for hypoglycemia and ketoacidosis, so ensure proper hydration and caloric intake. As exercise enhances insulin sensitivity, the quantity and duration of aerobic and anaerobic exercise and intensity of practices and games need to be assessed. In general: Short-term exercise = no insulin changes. Vigorous exercise may require 25% reduction in insulin with 15–30 g of carbohydrates before and every 30 min during exercise. Strenuous exercise = may require up to an 80% reduction in insulin with extra carbohydrates. Generally, monitor blood glucose frequently during exercise. Diabetic athletes typically perform best with glucose levels between 70 and 150 mg/dL.</td>

REHABILITATION OF SPORTS INJURIES

Participation in sports benefits children not only by promoting physical activity but also by the acquisition of motor and social skills. All sports participation, however, carries an inherent risk of injury. Injuries are classified as either acute or chronic. Chronic injuries occur over time as a result of overuse, repetitive microtrauma, and inadequate repair of injured tissue. When the demands of exercise exceed the body’s ability to recover, overuse injury may occur. Overuse injury accounts for up to 50% of all injuries in pediatric sports medicine. Risk factors for overuse may include year round participation, participation in more than one team at a time, early specialization in one sport, poor mechanics, and training errors such as increasing exercise volume, load, frequency, or intensity too quickly. To avoid overuse injury, athletes should train with a regular variety of resistance, power, speed, agility, skills, and distance. Adequate periods of rest and recovery should be incorporated into every training regimen in order to ensure proper healing of stressed tissues. Treatment measures such as corticosteroid or platelet-rich plasma injections are more commonly used in skeletally mature athletes.

Present trends in injury rehabilitation and prevention focus on core stability training and dynamic warm-up and stretching. Core exercises emphasize isometric holds that activate the core and pelvis. They utilize light single limb movements to challenge endurance over protracted time periods. Programs should be age appropriate and modified as needed to exercise in a pain-free range. The development of back pain during a core program signifies poor technique, overly complicated curriculum, or a prior back injury. Exercise programs can be obtained from the website resource: http://www.webexercises.com.

Dynamic warm-up and stretching programs concentrate on light movement prior to exercise. Dynamic programs use controlled, full active range of motion of each joint for an overall excitatory and stretching effect prior to exercise. The aim is to initiate light perspiration and increase heart rate, peripheral circulation, and connective tissue suppleness through simple excitatory activity. In contrast to traditional static stretching regimens in which athletes hold a stretching position for a distinct period of time, an appropriate dynamic curriculum will incorporate aerobic activity and moving stretches into sport-specific movement preparation. Areas of focus include joint range of motion, proprioception, coordination, balance, flexibility, muscular contraction, and stimulation of the central nervous system and energy resources. For example, athletes may work through a series of exercises such as side shuffle, high knee stepping, bear crawls, and double-leg hopping over cones three times. Static stretching is appropriate after exercise is complete. A useful website to design a dynamic stretching program can be found at: http://www.webexercises.com.

Acute injuries or macrotrauma are one-time events that can cause alterations in biomechanics and physiology. Response to an acute injury occurs in predictable phases. The first week is characterized by an acute inflammatory response. During this time, initial vasodilatation is followed by vasoconstriction. Chemical mediators of inflammation are released, resulting in the classical physical findings of local swelling, warmth, pain, and loss of function. This phase is essential in healing of the injury. The proliferative phase occurs over the next 2–4 weeks and involves repair and clean-up. Fibroblasts infiltrate and lay down new collagen. Last, the maturation phase allows for repair and regeneration of the damaged tissues.

The management of acute sports injuries focuses on optimizing healing and restoring function. The goals of immediate care are to minimize the effects of the injury by reducing pain and swelling, to educate the athlete about the nature of the injury and how to treat it, and to maintain the health and fitness of the rest of the body. The treatment for an acute injury is captured in the acronym PRICE:

- Protect the injury from further damage (taping, splints, braces)
- Rest the area
- Ice
- Compression of the injury
- Elevation immediately
Nonsteroidal anti-inflammatory drugs (NSAIDs) may reduce the inflammatory response and reduce discomfort. These medications may be used immediately after the injury. When safely and appropriately managed, therapeutic use of physical modalities, including early cold and later heat, hydrotherapy, massage, electrical stimulation, iontophoresis, and ultrasound, can enhance recovery in the acute phase.

The recovery phase can be lengthy and requires athlete participation. Physical therapy prescription is a common treatment modality. Initial treatment is focused on joint range of motion and flexibility. Range-of-motion exercises should follow a logical progression of starting with passive motion, then active assistive and finally active movement. Active range of motion is initiated once normal joint range has been reestablished. Flexibility exercises, particularly dynamic stretches, are sport-specific and aimed at reducing tightness of musculature. Strength training can begin early in this phase of rehabilitation. Initially only isometric exercises (static muscle contraction against stable resistance without movement of a joint or change in length of a muscle) are encouraged. As recovery progresses and flexibility increases, isotonic (change in length of a muscle without varying resistance) and isokinetic (change in length of a muscle against variable resistance without varying speed) exercises can be added to the program. These should be done at least three times per week.

As the athlete approaches near-normal strength and is pain-free, the final maintenance phase can be introduced. During this phase, the athlete continues to build strength and work on endurance. The biomechanics of sport-specific activity need to be analyzed and retraining incorporated into the exercise program. Generalized cardiovascular conditioning should continue during the entire rehabilitation treatment. Typically, return-to-play guidelines after an injury include the attainment of full joint range of motion, nearly full and symmetric strength, full speed, and nearly full sport-specific agility and skill.

HEAD & NECK INJURIES

Head and neck injuries occur most commonly in contact and individual sports. The sports with the highest incidence of brain injury are football, bicycling, baseball, and horseback riding. Concussions most commonly occur in football, ice hockey, rugby, boxing, basketball, lacrosse, soccer, bicycling, judo, and baseball/softball. The optimal treatment of these injuries has not been established and multiple guidelines have been developed. As a general rule, treatment of head and neck injuries in young children should be more conservative because of their developing central nervous systems.
1. Concussion

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Symptoms appear after a traumatic blow causing sudden movement to the head.
- Headache, dizziness, light or noise sensitivity, balance issues, fatigue, fogginess, concentration difficulties are commonly present.

- Focal neurologic symptoms should raise concern for acute intracranial process or bleed and prompt more immediate workup.
- Efforts should be made to normalize activities of daily life as soon as possible by following the return to learn steps.
- Return to contact sports should take place only after the patient is back to normal with no symptoms and has successfully completed the return to play protocol.

</tbody>
</table>
Concussion is a complex process that occurs when a direct blow to the body or head translates forces into the brain, causing a transient alteration of neurologic function. Even in the presence of neurologic symptoms, concussions are usually not associated with structural changes in brain tissue detectable by standard imaging studies. Instead, they may cause metabolic and vascular changes in cerebral tissues. Consequently, there are complex alterations in physiologic function, such as catecholamine surges and failure of cerebral blood flow autoregulation, leading to the common symptoms we ascribe to this type of injury. Symptoms may appear and evolve over the first few hours after injury. Confusion, headache, visual disturbance, posttraumatic amnesia, and balance problems are common symptoms. It is important to note that concussion does not have to involve loss of consciousness. Concussion should be suspected in any athlete with somatic, cognitive, or behavioral complaints as listed in Table 27–4. Observers may notice physical signs, behavioral changes, or cognitive impairment in the injured athlete. Diagnosis may be aided by the use of the Sport Concussion Assessment Tool v.3 (SCAT3) and the Child-SCAT3 (ages 5–12 years), which also provide standardized patient hand-outs (available at http://bjsm.bmj.com/content/47/5/259. full.pdf and http://bjsm.bmj.com/content/47/5/263.full.pdf).

Regardless of level of participation or elite status, any athlete suspected of sustaining a concussion in a practice or collision sports, and many states have passed legislation requiring medical assessment of concussed youth and medical clearance for return to play. Current expectations are that children should return to school prior to participation, symptoms should be resolved both at rest and during exercise without the aid of medication and a graduated return-to-play protocol should be completed. Return to play is a six-step progression with each step lasting 24 hours: (1) when asymptomatic at rest for 24 hours, progress to (2) light aerobic exercise, followed by (3) sport-specific exercise, then begin (4) noncontact drills, followed by (5) contact practice drills, and finally (6) release to game play. If any symptoms recur during any of the steps, the athlete should not move to the next stage and should rest for 24 hours, thereafter restarting at the previous step where the athlete was asymptomatic. Commonly, it is recommended that an athlete follow-up with a medical provider for clearance for return to contact or collision sports, and many states have passed legislation requiring medical assessment of concussed youth and medical clearance for return to play. Current expectations are that children should return to school prior to return to sport. In general, conservative return to play guidelines should be used in children.

Among commonly used assessment tools are the SCAT3, Standardized Assessment of Concussion (SAC), Balance Error Scoring System (BESS), computerized testing, and symptoms checklist (see Table 27–4). Neuropsychological testing may be helpful in assessing the cognitive function of concussed athletes, but it should not be used as the only source of clinical decision making. It may assist in management decisions for athletes with complex cases or severe or prolonged symptoms and is best performed and interpreted by a qualified neuropsychologist. Preseason testing may provide a comparison to help practitioners assess acute concussive status, but there is no solid

The long-term effects of concussions or contact/collision sports have yet to be established; specifically, a cause-and-effect relationship has not been proven between concussions and chronic traumatic encephalopathy (CTE). Second impact syndrome is a controversial diagnosis primarily based on anecdotal reports. There is no universal agreement on the existence of this reported phenomenon. Advocates endorse a rare but potentially deadly complication of repeated head injury, causing loss of vascular auto-regulation, catecholamine surge, increased cerebral blood pressure, and subsequent malignant cerebral edema without intracranial hematoma. Consequences include massive brain swelling and herniation leading to seizure, coma, and, possibly, death. Opponents suggest the phenomenon is actually the well-established condition of diffuse cerebral swelling, a known complication of head injury, particularly in younger individuals. The decision to retire an athlete from high risk or contact/collision sport is a sensitive and challenging one. There is currently little evidence to support a standardized approach to retirement decisions. However, considerations should include total number of concussions; increasing frequency; occurrence with serially less force; and prolonged, more severe, or permanent symptoms/signs.

Burners or stingers are common injuries in contact sports, especially football. The two terms are used interchangeably to describe transient unilateral pain and paresthesias in the upper extremity. These cervical radiculopathies or brachial plexopathies typically occur when the head is laterally bent and the shoulder depressed, causing exacerbation of a degenerative cervical disk or stenosis, a compressive injury to a cervical nerve root on the symptomatic upper extremity, or a traction injury to the brachial plexus of the ipsilateral shoulder. Symptoms include immediate burning pain and paresthesias down one arm generally lasting only minutes. Unilateral weakness in the muscles of the upper trunk—supraspinatus, deltoid, and biceps—also tends to resolve quickly, but can persist for weeks. The most important part of the workup is a thorough neurologic assessment to differentiate this injury from a more serious brain or cervical spine injury. The key distinguishing feature of the stinger is its unilateral nature. If symptoms persist or include bilateral complaints, headache, change in mental status, or severe neck pain, a diagnostic evaluation should include a careful neurological examination and possibly cervical spine radiographs, including flexion/extension views, magnetic resonance imaging (MRI) scans, and electromyography (EMG).

Treatment consists of removal from play and observation. The athlete can return to play once symptoms have resolved, neck and shoulder range of motion is pain-free, reflexes and strength are normal, and the Spurling test is negative. The Spurling test is performed by having the neck extended, rotated, and flexed to the ipsilateral...
shoulder while applying an axial load. Restriction of same day return to play should be considered in athletes with a history of multiple stingers, particularly if sustained in the same season. Preventative strategies include always wearing well-fitting protective gear, proper blocking and tackling techniques, and maintaining neck and shoulder strength. Long-term complications are possible, including permanent neurologic injury or repeated occurrence of stingers, which would necessitate further workup and possible lifetime exclusion from contact or collision sports.

SPINE INJURIES

As children have become more competitive in sports, spine injuries have become more common. Sports with a fairly high incidence of spine injuries include golf, gymnastics, football, dance, wrestling, and weightlifting. Back pain lasting more than 2 weeks indicates a possible structural problem that should be investigated.

Acute injury to the spine often results from an axial load injury. Patients present with focal tenderness of the thoracic or thoracolumbar spine. Evaluation includes plain radiography that may demonstrate anterior wedging of the thoracic vertebra, representing a compression fracture. When significant spinal tenderness or any neurologic abnormalities are present, radiographs are often followed by CT or MRI. Treatment of minor compression fractures includes pain control, bracing, rest from high-risk sports, and physical therapy. With appropriate rehabilitation, athletes can usually return to contact activity within 8 weeks.

1. Spondylolysis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Injury to the pars interarticularis.
- Usually presents as lower back pain with extension.

Spondylolysis is an injury to the pars interarticularis of the vertebral complex, resulting in a stress reaction or an acquired stress fracture. The pars interarticularis is the bony connection between the inferior and superior articulating facets. Injuries to the pars interarticularis, or pars defects for short, are present in 4%–6% of the population. In adolescent athletes, however, the incidence of spondylolysis in those presenting with lower back pain is close to 50%. As such, it should be high on the differential when evaluating lower back pain in this population. The incidence of pars defects in athletes such as gymnasts, dancers, divers, and wrestlers is significantly increased because of the repetitive flexion/extension motions combined with rotation. Repetitive overload results in stress fractures. Spondylolysis occurs at L5 in 85% of cases. The athlete presents with midline low back pain that is aggravated by extension, such as arching the back in gymnastics. There may be palpable tenderness over the lower lumbar vertebrae, with pain on the single leg hyperextension test (Stork test). Tight hamstrings are another common physical finding. Evaluation includes anteroposterior (AP) and lateral radiographs of the lumbar spine. Although oblique radiographic views of the lumbar spine are helpful to look for the so-called Scottie dog sign, they are falling out of favor because they do not significantly improve diagnostic accuracy and increase radiation exposure. Single photon emission computed tomography (SPECT) scan, CT scan, and MRI can be useful to determine the presence of an active spondylolytic lesion. Bone/SPECT scan shows stress reaction or pars injury before other radiographic changes. CT provides excellent definition of bony anatomy and can document healing. MRI is an alternative to detect pars interarticularis problems. With the use of high magnetic field strength and fat saturation techniques, high-resolution MRI images can now show subtle bone marrow edema of early stress injuries and are becoming popular, particularly for pediatric patients because of the lack of radiation exposure. There is currently no gold standard for the treatment of spondylolysis. The goal is to alleviate painful symptoms and allow the athlete a safe return to play. Management includes refraining from hyperextension and high-impact sporting activities, stretching of the hamstrings, and core and back stabilization exercises. Athletes can cross-train with low-impact activity and neutral or flexion-based physical therapy. Bracing is controversial. Outcome studies show similar results regarding return to sports and bony healing whether or not braces are worn. It is important to note also that clinical outcome does not necessarily correlate with healed pars fracture versus bony nonunions (when the fractured bone fails to heal). Satisfactory outcomes (asymptomatic patients and return to sports) can be achieved regardless of bony healing status. Typically, return to play is often delayed 8–12 weeks or longer based on clinical signs of healing. Most symptomatic spondylolysis improves with rest and activity modifications (with or without radiologic evidence of healing).
Once asymptomatic, an athlete can usually return to sports without restrictions. Surgery is reserved for refractory cases that fail conservative measures.

2. Spondylolisthesis

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Bilateral pars interarticularis injury resulting in forward slippage of one vertebra over the one below it.
- Usually presents as back pain with extension.
- Hyperlordosis, or possible step-off of lumbar spine.

When a bilateral pars stress fracture (spondylolysis) occurs, slippage of one vertebra over another causes a spondylolisthesis. Patients present with hyperlordosis, kyphosis, pain with hyperextension, and, in severe cases, a palpable step-off. A standing lateral radiograph is used to make the diagnosis and to monitor for any progression of slippage. These injuries are graded from 1 to 4 based on the percentage of slippage: grade 1 (0%–24%), grade 2 (25%–49%), grade 3 (50%–74%), and grade 4 (75%–100%).

Treatment is often symptom based. Asymptomatic athletes with less than 25% slippage often have no restrictions and are followed on a routine basis for radiograph assessment. Management of symptomatic spondylolisthesis requires a period of activity modifications, particularly protection from spine extension and impact activities, coupled with a regimen of stretching of the hamstrings and core and back stabilization exercises. Bracing may also be considered. Surgical intervention is considered for slippage greater than 50%, progressive spondylolisthesis, or intractable pain despite nonoperative treatment. If surgery is required, the athlete must understand that he or she cannot return to activities for at least 1 year and may not be able return to previous sporting activities.

3. Disk Herniation

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Back pain worse with flexion and sitting.
- Radiculopathy can be present.
- Positive straight leg raise.

Discogenic back pain accounts for a small percentage of back injuries in children. These injuries are almost unheard of in preadolescence. Back pain can originate from disk bulging, disk herniation, or disk degeneration. Most injuries occur at L4–L5 and L5–S1 vertebrae. Not all disk bulges found on MRI are symptomatic. In adolescents, most disk herniations are central rather than posterolateral. Risk factors include heavy lifting, excessive or repetitive axial loading of the spine, rapid increases in training, or trauma. Symptoms include back pain, which may be increased with activities such as bending, sitting, and coughing. Although not as common as in adults, radicular symptoms of pain down the leg can also occur and are often associated with large disk herniations. Evaluation includes physical and neurologic examinations, including straight leg testing, sensory testing, and checking reflexes. If symptoms persist, evaluation usually begins with radiographs and an MRI, which is the imaging test of choice for diagnosing disk herniation. EMG may also be considered in the presence of radiculopathy.

Treatment usually is conservative as most disk herniations, even if large, improve spontaneously. The athlete can rest the back for a short period, with avoidance of prolonged sitting, jumping, or hyperextension and hyperflexion of the spine, as these activities may increase pressure on the disk, leading to aggravation of symptoms. After a short period of rest, a structured physical therapy program should begin, focusing on core and pelvic stabilization, peripelvic flexibility and sports or activity specific conditioning. If symptoms persist, a short course of oral steroids or epidural steroid injection may be indicated. Surgery is recommended for patients who fail conservative therapy, have significant or progressive radiculopathy, or who have progressive neurologic deficit.

**SHOULDER INJURIES**

Shoulder injury is usually a result of acute trauma or chronic overuse. Acute injuries around the shoulder include contusions, fractures, sprains (or separations), and dislocations. The age of the patient affects the injury pattern, as younger patients are more likely to sustain fractures instead of sprains. Sprains (ligaments) and strains (muscle and tendon) are generally defined as low-grade soft tissue injuries that do not result in functional compromise of a structure.
1. Fracture of the Clavicle

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Injury by fall on to shoulder or outstretched hand.
- Severe pain in the shoulder.
- Tenderness, swelling, and/or deformity over clavicle.

Clavicular fractures occur from a fall or direct trauma to the shoulder. Focal swelling, deformity, and tenderness are present over the clavicle. The diagnosis is made by radiographs of the clavicle; the fractures are most common in the middle third of the bone.

Initial treatment is focused on pain control and protection with a sling and swathe. Early range of motion is permitted based on pain level. Progressive rehabilitation is important. Athletes cannot return to contact sports for 8–12 weeks. Absolute surgical indications for acute clavicular fractures include open fractures or neurovascular compromise. Fracture nonunion is unusual in young patients. However, there is recent evidence in the adult population recommending surgical stabilization for fractures that are very displaced or shortened. The role of acute surgical stabilization in the pediatric and adolescent population in regards to shortening is still being defined. Patients with recurrent fractures or nonunion typically will also require surgical fixation.

2. Acromioclavicular Separation

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Injury with fall on shoulder.
- Severe pain in the shoulder.
- Tenderness, swelling, and/or deformity over acromioclavicular joint.

A fall on the point of the shoulder is the most common cause of acromioclavicular separation. Tearing of the acromioclavicular joint capsule and possibly the coracoclavicular ligaments occurs. The injury is classified by the extent of the injuries to these ligaments. Athletes present with focal soft tissue swelling and tenderness over the acromioclavicular joint. More severe injuries are associated with deformity. Patients have a positive cross-arm test, in which pain is localized to the acromioclavicular joint. Radiographs are necessary in this setting to assess the degree of injury and to evaluate for a coexisting fracture or growth plate injury.

Treatment is supportive, with rest and immobilization in a sling followed by progressive rehabilitation. Return to activity can be accomplished in 1–6 weeks depending on the severity of the injury and the persistence of symptoms. Full range of motion and full strength must be achieved prior to being cleared to return to sports.

3. Fracture of the Humerus

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Injury with significant fall on outstretched arm.
- Severe pain in proximal humerus.
- Tenderness, swelling, and/or deformity over proximal humerus.

Fractures of the humerus occur from a severe blow or fall on the shoulder. Pain and swelling are localized to the proximal humeral region. The fractures can include the physes or may be extraphyseal. A significant amount of displacement and angulation can be tolerated in this location because of the young athlete’s potential for remodeling and because of the intrinsic range of motion of the shoulder. Careful assessment of the brachial plexus and radial nerves are needed to rule out associated nerve damage.

Treatment consists of a sling for 4–6 weeks followed by progressive rehabilitation with return to play at 8–12 weeks when bony healing, full range of motion, and strength have been achieved.

4. Acute Traumatic Anterior Shoulder Instability (Anterior Shoulder Dislocation/Subluxation)

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Injury with an abducted and externally rotated arm.
- Severe pain in the shoulder.
- Squared-off shoulder on examination.
- Reduced range of motion of the shoulder.

A fall on the point of the shoulder is the most common cause of acromioclavicular separation. Tearing of the acromioclavicular joint capsule and possibly the coracoclavicular ligaments occurs. The injury is classified by the extent of the injuries to these ligaments. Athletes present with focal soft tissue swelling and tenderness over the acromioclavicular joint. More severe injuries are associated with deformity. Patients have a positive cross-arm test, in which pain is localized to the acromioclavicular joint. Radiographs are necessary in this setting to assess the degree of injury and to evaluate for a coexisting fracture or growth plate injury.

Treatment is supportive, with rest and immobilization in a sling followed by progressive rehabilitation. Return to activity can be accomplished in 1–6 weeks depending on the severity of the injury and the persistence of symptoms. Full range of motion and full strength must be achieved prior to being cleared to return to sports.
Acute traumatic anterior shoulder instability occurs when significant force is applied to the abducted and externally rotated shoulder. Most often, the humeral head is dislocated in an anterior and inferior direction. The patient has severe pain and a mechanical block to motion. Some patients will spontaneously reduce within seconds or minutes of their injury. Most patients, however, require immediate closed reduction on the field or in the emergency room. Radiographs are helpful to confirm the position of the humeral head as well as to evaluate for coexisting fracture. MRI may be required for accurate visualization of fractures and cartilaginous injury.

Optimal follow-up treatment for glenohumeral dislocation in young athletes has not been established. Initially, the shoulder is immobilized for comfort. Range-of-motion exercises and progressive rehabilitation are initiated. Prolonged immobilization does not decrease the risk of recurrence and is discouraged. Return to play in-season can be considered with appropriate counseling. Because of the high risk of recurrence, options for treatment should be individualized, with consideration given to both nonoperative and surgical management.

5. Rotator Cuff Injury

Shoulder injuries are often a consequence of repetitive overuse and tissue failure. Rotator cuff tendonitis and bursitis are the most commonly observed rotator cuff injuries in youth sports. Rotator cuff tears in children and adolescents are exceedingly rare. These overuse injuries typically occur in sports requiring repetitive overhead motions. Muscle imbalances and injury can cause the position of the humeral head to be abnormal, which may cause entrapment of the supraspinatus tendon under the acromial arch. Patients with nontraumatic shoulder instability due to ligamentous and capsular laxity (also known as multidirectional instability) are prone to overuse rotator cuff injury. These athletes present with chronic pain in the anterior and lateral shoulder, which is increased with overhead activities. Diagnostic workup includes plain radiographs and an outlet view to look for anatomic variability. The rehabilitation of this injury is geared toward reduction of inflammation, improved flexibility, and core stabilization and strengthening of the scapular stabilizers and rotator cuff muscles. A biomechanics evaluation can assist athletes in the recovery process by building sport-specific skills and eliminating substitution patterns. Surgery is rarely indicated.

6. Little League Shoulder

Proximal humeral epiphysitis, or “Little League shoulder,” is an overuse injury that occurs in children aged 11–14 years who play overhead sports such as baseball. The patient presents with activity-related pain in the lateral aspect of the proximal humerus. Examination often shows tenderness over the proximal humerus. Absence of findings on office examination does not preclude this diagnosis. The hallmark feature is pain with throwing. Radiographs show widening, sclerosis, and irregularity of the proximal humeral physis. Comparison views are often helpful when considering this diagnosis.

Treatment consists of rest from throwing or other aggravating activity. Physical therapy is initiated during the rest period. Return to play can only be considered after a period of rest has significantly decreased the pain and the athlete has proceeded through a progressive throwing program. Healing can take several months. Signs of radiographic healing may lag behind the athlete’s clinical progress and normal radiographs are not necessarily required to return an athlete to play. Permanent sequelae such as fracture, growth arrest, or deformity is extremely rare but can occur in chronic cases that are not treated appropriately.

ELBOW INJURIES

Injuries in the elbow are quite common and have both chronic and acute etiologies. They often occur in athletes involved in throwing or overhead sports. Although acute
injuries to the elbow are common, chronic overuse injuries are becoming more and more prevalent in young athletes. Risk factors leading to overuse elbow injury include single sport specialization, year-round participation, longer competitive seasons, insufficient rest, and poor biomechanics. The term Little League elbow is used loosely to encompass a variety of causes of elbow pain in young throwing athletes. These injuries include medial epicondylitis, apophysitis, medial epicondyle avulsion fracture, Panner disease, and osteochondritis dissecans (OCD) of the capitellum. It is intended, however, to refer to medial epicondyle apophysitis, an overuse elbow injury resulting from repetitive valgus stress from overhead throwing.

When the elbow is evaluated, it is helpful to divide the examination into specific anatomic areas, discussed as follows.

1. **Medial Epicondyle Apophysitis (Little League Elbow)**

   - **ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**
     - Participation in a throwing sport.
     - Pain over the medial epicondyle, especially with pitching.
     - Tenderness and swelling of medial elbow.

   *Little League elbow* is a traction injury to the medial epicondylar physis, which develops in young overhead throwing athletes, particularly baseball pitchers, between the ages of 9 and 12 years. The biomechanical forces generated around the elbow during throwing, namely repetitive valgus stress, can result in shearing, inflammation, traction, and abnormal bone development. The symptoms are primarily swelling, medial elbow pain, performance difficulties, and weakness. The pain localizes to the medial epicondyle, which may be tender to palpation, and worsened with valgus stress. Wrist flexion and forearm pronation may increase symptoms. The physician should inquire about the exposure to throwing, including pitch counts, the number of practices and games, and the duration of the season. Workup includes elbow radiographs, with comparison films of the unaffected side, to look for widening of the apophysis. Rarely, MRI is used to confirm the diagnosis.

   Treatment of the injury includes complete rest from throwing activities. It is not uncommon for a player to be restricted from throwing for up to 6 weeks. Competition can be resumed once the player is asymptomatic and has progressed through a graduated, age-appropriate throwing program. The key approach for this injury is prevention. Children should be properly conditioned and coached in correct throwing biomechanics. Guidelines for Little League pitching limits in youth baseball have been developed and are outlined in Table 27–5.

2. **Panner Disease**

   - **ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**
     - Participation in a throwing sport.
     - Pain over the lateral elbow.
     - Swelling and flexion contracture.

   Panner disease refers to developmental osteochondrosis of the capitellum that results from overuse injury. The lesion involves disordered ossification of the capitellum, which is the lower end of the humerus that articulates with the radius. This condition occurs in children aged 5–12 years who play sports that involve overhead throwing and in gymnasts. The repetitive lateral compressive forces from loading the elbow in these sports compromises the blood supply to the growing epiphysis, leading to degeneration of the ossification center, or osteochondrosis. The child may have dull aching in the lateral elbow that worsens with throwing. Swelling and reduced elbow extension usually are present. Radiocapitellar compression test will also elicit pain—with elbow fully extended, arm is actively pronated and supinated. Radiographs show an abnormal, flattened capitellum, with fragmentation and areas of sclerosis. This should be distinguished from OCD of the capitellum, which typically occur in older children (see as follows). Treatment is conservative, using rest, ice, and splinting. Avoid activities that load the elbow for 3–6 months. The child can return to play once symptoms resolve, and there is evidence of healing on
follow-up radiographs. The natural history of this condition is one of complete resolution of symptoms and, ultimately, normal ossification of the capitellum.

3. Ulnar Collateral Ligament Tear

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Sudden forceful tensile stress on ligament from a fall or from valgus stress to elbow during overhead throw.
- Feeling a pop or sensation of elbow giving out.
- Medial elbow pain.
- Tenderness distal to medial epicondyle.

Once the medial epicondylar physis closes in a skeletally mature athlete, valgus forces are then transmitted to the ulnar collateral ligament, resulting in a sprain or tear. Patients present with medial elbow pain and are often unable to fully extend the elbow. Examination reveals tenderness just distal to the medial epicondyle, and there may be instability with valgus stressing. Treatment is conservative, including rest, ice, and physical therapy directed at range of motion and strengthening. Surgery may be suggested for those with persistent pain or instability and who desire to continue participating in overhead sports.

4. Osteochondritis Dissecans

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Participation in a throwing sport.
- Pain over the lateral elbow, especially with pitching.
- Tenderness over radiocapitellar joint.
- Elbow flexion contracture.

Lateral elbow pain in a slightly older throwing athlete, usually aged 13–15 years, can be secondary to osteochondritis dissecans (OCD), which is a more worrisome diagnosis than Panner disease. Unlike Panner disease, which is self-limiting, OCD lesions can lead to permanent destruction of the bone. It is an injury to the subchondral bone and its overlying articular cartilage. Although it can involve different sites of the elbow, including the olecranon, radial head, or trochlea, it most commonly affects the capitellum. Repetitive valgus compressive forces can lead to avascular necrosis of the capitellum, which can ultimately result in the formation of loose bodies in the joint. The athlete presents with lateral pain, swelling, lack of full extension, and occasionally locking. Radiographs show lucency of the capitellum with surrounding sclerotic bone. MRI can more fully delineate the lesion. The prognosis for high-grade lesions is guarded.

A child with OCD should be seen by either a sports medicine specialist or an orthopedic surgeon with expertise in upper extremity injuries. Treatment is based on stability of the lesion and can be either conservative or surgical. For early or stable OCD lesions, particularly in skeletally immature individuals, management includes throwing activity restrictions and range of motion exercises. More advanced lesions or those with persistent symptoms despite conservative treatment may require surgical intervention.

5. Lateral Epicondylitis

Lateral epicondylitis (also known as tennis elbow) is common in skeletally mature athletes participating in racquet sports. It is a tendinopathy of the extensor muscles in the forearm, which inserts onto the lateral epicondyle causing lateral elbow pain. The pain is increased by wrist extension. Initial treatment is aimed at inflammation control. Stretching and strengthening of forearm muscles are the primary interventions during the subsequent phases. Stroke mechanics may need to be altered and a forearm brace used to decrease the forces in the extensor muscles.

6. Posterior Elbow Pain

Posterior elbow pain is uncommon. Etiologies include dislocations, impingement, fractures, triceps avulsions and tendinitis, olecranon apophysitis, and olecranon bursitis.

HAND & WRIST INJURIES

The hand and wrist are the most common area of injury in children and account for a large proportion of emergency room visits. All hand and wrist injuries have the potential for serious long-term disability and deserve thorough evaluation. A thorough neurovascular examination as well as evaluation of rotational or angular deformity or malalignment is critical. Examples of complications include loss of range of motion, dysfunction, deformity, limb length discrepancy, and arthritis.
1. Distal Phalanx Injury

Tuft injury requires splinting for 3–6 weeks or until the patient is pain free. If there is significant displacement, a surgical K-wire can be used for reduction. Nail-bed injury often requires nail-bed suturing, splinting, and drainage of subungual hematomas. Nail avulsions should be replaced into the nail fold, and if not possible, a substitute material should be interposed into the nail bed as a stent. Patients with nail-bed injuries should be advised that nail regrowth may appear irregular or may not occur at all.

2. Distal Interphalangeal Injury

Mallet finger or extensor tendon avulsion occurs more commonly in ball-handling sports. The mechanism of injury is an axial load or forced flexion against an actively extending finger, causing avulsion fracture or rupture of the extensor digitorum tendon. Athletes present with a flexion contracture at the distal interphalangeal (DIP) joint and inability to actively extend the distal phalanx. Referral to an orthopedic surgeon is necessary. Conservative treatment consists of splinting in extension for 4 weeks for fractures and 6–8 weeks for tendon rupture. Surgery may be required if the initial fracture involves greater than 30% of the joint space or poor healing with loss of function occurs.

Jersey finger, or flexor tendon avulsion, occurs in contact sports, particularly American football. The mechanism of injury is forced extension against an actively flexed finger. The fourth ("ring") finger is the most commonly injured digit. Athletes present with tenderness, swelling, and inability to flex at the DIP. The examiner can test the function of the flexor tendon by holding the proximal interphalangeal joint in extension while having the injured athlete attempt flexion at the DIP joint. The injured finger should be splinted in a comfortable position and immediately referred to an orthopedic surgeon, as definitive treatment is often surgical.

3. Thumb Injury

Gamekeeper’s or skier’s thumb is an injury to the ulnar collateral ligament from forced abduction of the thumb metacarpophalangeal (MCP) joint. It is a common skiing injury to those who fall while holding on to their ski poles. Patients will complain of pain over the medial aspect of the MCP joint and pain with apposition or pinching. If a radiograph shows an avulsed fragment that is displaced less than 2 mm, a thumb spica cast can be used. If there is no fragment, less than 35 degrees of lateral joint space opening, or less than 15 degrees difference in joint space opening compared to the uninjured thumb, a spica cast for 4–6 weeks is indicated. Surgery is required for more serious injuries.

4. Hand Fractures

All finger fractures should be assessed for growth plate involvement, rotation, angulation, and displacement. If stable and not displaced, these fractures can be splinted for 3–4 weeks and buddy-taped for immediate return to sports. However, spiral or oblique fractures of the middle phalanx, intra-articular fractures, and severely angulated physeal fractures are considered unstable and should be referred to an orthopedic surgeon.

Boxer’s fracture is a neck fracture of the fourth or fifth metacarpal, typically caused by poor punching technique or punching into a hard surface. Less than 40 degrees of angulation in the fourth or fifth metacarpals is acceptable. Assessment of displacement and rotational deformity is critical, as displaced or rotated fractures require reduction and fixation. Prior to definitive treatment with hand-based casting for 4 weeks, boxer’s fractures may be temporarily immobilized with an ulnar gutter splint with the MCP joints flexed to 70 degrees.

5. Wrist Injury

Most swollen wrists without evidence of gross deformity or instability can be splinted temporarily for several days. Radial and ulnar fractures, which are fairly common in children, must be ruled out. Particular attention should be paid to the growth plates and the scaphoid bone. Typically, distal radius and ulna fractures require casting for 3–6 weeks in either a short or long arm cast, depending on the involvement of one or both bones and the severity of displacement or angulation. Torus, or buckle, fractures may be placed in a rigid wrist brace or short arm cast for 3–4 weeks. Scaphoid fractures are caused by a force applied to a hyperextended wrist, most commonly a fall onto an outstretched hand. Despite normal radiographs, if evidence of snuffbox tenderness and swelling is present, there is tenderness along the volar aspect of the scaphoid, or there is pain with radial wrist deviation or active wrist range of motion; the wrist must be further evaluated, either by MRI acutely or immobilized for 10 days and then reassessed both clinically and with follow-up radiographs. A nondisplaced scaphoid fracture requires at least 6 weeks of immobilization in a thumb spica cast. Nonunion can occur, particularly in fractures of the proximal pole of the scaphoid, related to the poor blood supply of this carpal bone. Displacement requires operative management. Gymnast’s wrist is chronic wrist pain due to repetitive overloading of the distal radial physis. Athletes complain of dorsal wrist pain, worsened with weight bearing on the affected upper extremity or active extension of the wrist. This overuse stress injury may cause long-term growth abnormalities or degenerative wrist joint changes, which may ultimately require surgical intervention. Athletes should be placed in a rigid wrist brace or short arm cast for
4 weeks and undergo a period of relative rest and activity modification.

HIP INJURIES

Because the pelvis and hip articulate with both the lower extremities and the spine, this area is rich in ligaments, muscle attachments, and nerves. Injuries in young children are rare, but sprains, strains, and avulsion fractures can occur. Additionally, athletes can be susceptible to overuse injury involving the hip.

1. Hip Avulsion Fractures

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► Fractures at apophyseal areas.
► Pain with weight bearing.
► Focal pain over the site of injury.

Avulsion fractures around the hip in adolescents occur at apophyseal regions such as the ischial tuberosity, anterior superior iliac spine, anterior inferior iliac spine, and iliac crest. The mechanism of injury is a forceful, unbalanced muscle contraction that causes avulsion of the muscle tendon insertion. The athlete presents with a history of an acute traumatic incident; often a “pop” is felt and the athlete is immediately unable to bear weight. Range of motion of the hip is limited secondary to pain and focal tenderness is present over the apophysis.

Treatment is conservative. Surgical management is rarely required even in displaced fractures. The athlete is typically placed on crutches for the first couple of weeks for pain control and to normalize gait. After the acute phase, an athlete can progress to weight bearing as tolerated. The rehabilitation phase focuses on regaining motion, flexibility training and pelvic, and core strengthening. Progressive return to activity can often be accomplished in 4–6 weeks, if full range of motion, full strength, and sport-specific skills have been achieved.

2. Slipped Capital Femoral Epiphysis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► Pain in the hip or knee, or both.
► Loss of internal rotation of the hip.
► Radiographs in the frog-leg position show widening of the physis and epiphyseal slippage.

Slipped capital femoral epiphysis occurs in children aged 11–16 years. The physis is weakened during times of rapid growing and is susceptible to shearing failure either acutely secondary to a traumatic injury or insidiously from chronic overload. Patients complain of groin, thigh, or knee pain and often have a limp. Examination shows painful range of motion of the hip, limited internal rotation, and obligatory external rotation when the hip is flexed. Radiographs include AP and frog-leg lateral films, which demonstrate widening of the physis and epiphyseal slippage or displacement of the femoral head relative to the femoral neck.

Treatment consists of immediate non-weight-bearing and urgent referral to an orthopedic specialist for open reduction and internal fixation. Failure to identify this injury can result in permanent hip deformity and damage resulting in early arthritis. Rehabilitation is a component of the postsurgical treatment. Return to activity is progressive over months. (See also Chapter 26.)

3. Acetabular Labral Tears

Acetabular labral tears are an increasingly recognized cause of anterior hip and groin pain in athletes. The majority of hip labral tears occur as a result of some underlying hip disorder such as femoroacetabular impingement (FAI) or hip dysplasia. Because of the stress and range of motion requirements for most athletics, these injuries tend to present and be more symptomatic in the athletic population. Athletes with this injury typically do not report an acute traumatic event that precipitated their symptoms. Symptoms often develop insidiously rather than acutely. Athletes present with deep anterior hip or groin pain that worsens with activity and is resistant to treatment. Radiographic findings can be normal. An MRI arthrogram is used to demonstrate the tear. Treatment typically starts conservatively and requires rest and physical therapy. Ultimately, treatment is tailored
to the athlete’s particular needs and symptoms. Arthroscopy to repair the tear and address any underlying structural issue that caused the tear is often required.

4. Adductor Strain

An adductor strain or a groin pull is generally caused by forced abduction during running, falling, twisting, or tackling. Sports that require quick directional changes place athletes at risk for these types of injuries. The associated pain is in the adductor muscle. There is often pain with hip adduction or flexion and tenderness over the adductor tubercle. Treatment includes rest, ice, and protection—often with crutches, and strengthening of the muscle when it heals.

5. Hamstring Strain

Hamstring strain is a common injury in athletes. The majority of these injuries occur in the muscle belly and can be treated successfully with nonoperative management. The mechanism of injury is forced extension of the knee or directional changes. Typically, the athlete with a hamstring strain suddenly stops playing and grabs the back of the thigh. There are three grades of injury. Examination reveals pain on palpation of the muscle and occasionally a defect. Pain also occurs with knee flexion against resistance.

Initial treatment is focused on minimizing swelling, bruising, and pain. The thigh should be iced and compression applied. In moderate and severe injuries, crutches may be needed for a short duration. The athlete can walk as soon as he or she can tolerate the activity. It is particularly important to stretch the hamstring because, as a two-joint muscle, it is more susceptible to injury than other types of muscle. Eccentric strengthening is an important component of rehabilitation.

6. Quadriceps Contusion

Quadriceps contusion is caused by a direct injury to the muscle that causes bruising, swelling, and pain. The amount of damage is directly related to the amount of force. The anterior and lateral thigh regions are most commonly injured, often in contact sports such as football and lacrosse.

Treatment is rest, ice, and protection for the first 24 hours. The knee should be kept in a fully flexed position. Two to 3 days after the injury, range-of-motion exercises may begin in both flexion and extension. Once 120 degrees of motion has been established and movement does not cause pain, the athlete may return to competitive activity. If the muscle remains firm on examination after 2 weeks, radiographs of the thigh should be obtained to rule out myositis ossificans, an abnormal deposition of calcium in the muscle that may be induced by aggressive stretching of the muscle too early in the clinical course.

7. Hip Dislocation

The hip is a very constrained joint and is inherently very stable. Therefore, hip dislocations are very rare and typically occur only in high energy or forceful injuries. Most hip dislocations occur in the posterior direction. Athletes with this injury typically have severe pain and any motion of the hip or leg is poorly tolerated. Classically, these athletes present with an acutely painful hip following a major impact and the hip is locked in flexion, adduction, and internal rotation. Hip dislocations in skeletally mature athletes are often associated with acetabular and femoral neck fractures. The preadolescent, skeletally immature competitor may have an isolated dislocation without fracture. Hip radiographs and advanced imaging such as a CT or MRI scan are needed to completely evaluate the injury.

This injury is an emergency. The athlete should be transported immediately to the nearest facility that has an orthopedic surgeon available. Severe bleeding, avascular necrosis, and nerve damage can result with delay in relocation. Most athletes can be relocated in a closed fashion. Once reduction has been established in an uncomplicated case, protected weight bearing on crutches for 6 weeks is recommended followed by another 6 weeks of range-of-motion and strengthening exercises. An athlete may return gradually
9. Iliotibial Band Syndrome

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Overuse running injury.
- Pain over lateral knee or hip.
- Positive Ober test.

Iliotibial (IT) band syndrome and associated trochanteric bursitis result when the bursa and IT band become inflamed because of repetitive friction from the underlying greater trochanter and lateral femoral condyle. This condition can cause pain when the hip or knee is flexed as a result of reduced flexibility of the iliotibial band and gluteus medius tendons. The bursa is a structure that normally allows for improved motion by reducing friction but becomes pathologic in this condition. Movement is painful and may be limited. Pain is reproduced when the hip or knee is actively flexed from a fully extended position. Patients may also have a positive Ober test. The Ober test is used to measure flexibility of the IT band. The patient lies on his or her side with the affected leg on top. The examiner stabilizes the pelvis with one hand while the other hand moves the tested leg into knee flexion, hip abduction and extension and then lowers the leg into adduction until it stops via soft tissue stretch, posterior rotation of the pelvis, or both. The test is positive if the tested leg fails to adduct parallel to the table in a neutral position.

Initial treatment is to alter the offending activity and then start a stretching program geared at the iliotibial band and hip abductors. Core and pelvic stabilization are also important. Ultrasound can be beneficial and corticosteroid injections may be used after conservative treatment has failed.

10. Femoral Neck Fractures

Femoral neck fractures (stress fractures) are generally the result of repetitive microtrauma. They commonly occur in running athletes who have rapidly increased their mileage. Athletes with this type of injury present with persistent pain in the groin and pain with internal and external rotation. Symptoms often are present with sports, but as the fracture progresses, symptoms often develop during activities of daily living. Athletes with a history of previous stress fracture, disordered eating, or any disorder of calcium metabolism and groin pain should alert the provider to the possibility of this diagnosis. Special attention to the risk of stress fracture should be given to the female athlete with the triad of energy imbalance and possible disordered eating, amenorrhea or oligomenorrhea, and low bone density.

On physical examination, range of motion may be limited in hip flexion and internal rotation. A limp may be present. Pain with hopping on the affected leg is universally present. If plain radiographs are negative, an MRI or a bone scan is indicated.

Treatment is based on the type of fracture. A tension-sided fracture (on the superior aspect of the femoral neck) generally requires internal fixation to prevent femoral displacement and reduce the risk of avascular necrosis. A compression fracture (on the inferior aspect of the femoral neck) is less likely to be displaced; treatment is conservative and involves resting the hip until it heals. Cardiovascular conditioning can be maintained easily through nonimpact exercises and activity.

KNEE INJURIES

Knee injuries are some of the most common sports-related problems. The knee is stabilized through a variety of ligaments, tendons, and the menisci. Knee injuries can be divided into two groups: those resulting from acute or chronic causes. Acute injuries occur during a well-defined traumatic incident. The mechanism of injury is an important historical feature, although many young patients have difficulty describing the details of the inciting event. The onset of rapid swelling after a traumatic event indicates the presence of a hemarthrosis and likely internal derangements such as fracture, rupture of the anterior cruciate ligament (ACL), meniscal tear, or patellar dislocation.

1. Anterior Knee Pain

The most common knee complaint is anterior knee pain. This complaint can have multiple etiologies but should always include hip pathology as a possible source.
Patellofemoral dysfunction (defined as follows) is a common cause of anterior knee pain. The differential diagnosis of anterior knee pain is extensive and requires a thorough examination. The following are the most common knee diagnoses responsible for anterior knee pain.

A. Patellofemoral Overuse Syndrome

Patellofemoral overuse syndrome occurs during running and sports that involve repetitive stress in the lower extremity. The athlete presents with activity-related pain in the anterior knee. In young athletes, it is occasionally associated with swelling and crepitus of the knee joint.

Evaluation of these injuries is comprehensive and requires a “top-down” evaluation of the athlete’s leg from the hip to the foot. Most athletes with this condition, regardless of level or physical condition, typically have hip/core weakness that results in altered knee biomechanics. A comprehensive evaluation of hip alignment and rotation, muscle development, tightness in the hamstrings and iliotibial band, and foot mechanics is necessary to fully understand and treat the cause of this disorder. Most athletes with this complaint often have a multifactorial cause for their symptoms.

Treatment should be geared toward identifying the cause. Often, athletes are overtraining and need to modify current activities. Cross-training may help. Addressing hip and pelvic stability is now a mainstay of treatment for this disorder. Stretching and strengthening of the hamstrings and quadriceps are recommended. The use of braces providing proprioceptive feedback during competition is controversial.

B. Patellar Tendonitis (“Jumper’s Knee”)

Patellar tendonitis is an overuse injury is caused by repetitive loading of the quadriceps during running or jumping. This diagnosis is common in jumping sports such as basketball and volleyball. Tenderness is located directly over the patellar tendon at its insertion site at the inferior pole of the patella. Physical therapy, icing, and activity modification can help facilitate healing.

C. Osgood-Schlatter Disease (Tibial Tubercle Apophysitis)

Osgood-Schlatter Disease is caused by the recurrent traction on the tibial tubercle apophysis (growth plate) that occurs in jumping and running sports. Fragmentation and microfractures of the tibial tubercle occur during its time of rapid growth. The condition occurs in the pre-teen and adolescent years and is most common in boys aged 12–15 years and girls aged 11–13 years. Pain is localized to the tibial tubercle and is aggravated by activities using eccentric quadriceps muscle movement. The pain can become so severe that routine activity must be curtailed. Radiographs typically demonstrate fragmentation or irregular ossification of the tibial tubercle.

Typically, the condition resolves spontaneously as the athlete reaches skeletal maturity. In the interim, pain control using NSAIDs is indicated. Physical therapy and stretching the hamstrings and application of ice after workouts are helpful.

D. Sinding-Larsen-Johansson Disease (Apophysitis of the Inferior Pole of the Patella)

Sinding-Larsen-Johansson Disease involves a process similar to that in Osgood-Schlatter disease but occurs in younger athletes between ages 9 and 12 years. Traction from the patellar tendon on the inferior pole of the patella results in fragmentation of the inferior patella that is often obvious on a lateral knee radiograph. Treatment and prognosis is similar to Osgood-Schlatter disease.

Treatment

The treatment of the above knee disorders is similar. As with many injuries, control of pain and inflammation is essential. This begins with relative rest from offending activity and application of ice. Alignment problems and mechanics across the anterior knee can be improved with an effective rehabilitation program that includes flexibility and strengthening. Quadriceps, pelvic, and core strengthening are all important components of this program. Orthotics, in theory, can have an impact on mechanics across the knee joint if they correct excessive pronation or supination. Knee bracing is controversial and the major benefits are proprioceptive feedback and patellar tracking. Return to activity is often based on symptoms.

2. Posterior Knee Pain

Posterior knee pain often results from an injury to the gastrocnemius-soleus complex caused by overuse. Other causes include a Baker cyst (benign synovial fluid filled cyst in the posterior aspect of the knee), tibial stress fracture, or tendonitis of the hamstring. Treatment is rest, ice, and strengthening exercises after symptoms have improved. Intra-articular injuries such as meniscal tears and cartilage injuries can also cause posterior knee pain and should be considered if symptoms do not improve.
3. Meniscal Injuries

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Medial or lateral knee pain.
- Effusion and joint line tenderness.
- Feeling of locking or of the knee giving way.
- Positive McMurray and Thessaly tests.

The meniscus of the knee cushions forces in the knee joint, increases nutrient supply to the cartilage, and stabilizes the knee. Most injuries are related to directional changes on a weight-bearing extremity. Medial meniscus injuries have a history of tibial rotation in a weight-bearing position. This injury happens frequently in ball-handling sports. Lateral meniscus injuries occur with tibial rotation with a flexed knee, as in exercises such as squatting or certain wrestling maneuvers. These injuries are uncommon in children younger than 10 years.

**Clinical Findings**

The athlete with such an injury has a history of knee pain, swelling, snapping, or locking and may report a feeling of the knee giving way. Physical examination often reveals effusion, joint line tenderness, and a positive McMurray hyperflexion-rotation test or positive Thessaly test. The McMurray test is performed by having the examiner place his/her fingers across the joint lines while flexing the knee maximally. The knee is then rotated while it is brought out into extension. A positive test is evoked when the patient reports pain and the examiner feels an associated click or catch along the joint line. The Thessaly test is performed by having the patient stand on the injured leg. The examiner supports the patient by holding his or her outstretched arms. The patient is instructed to flex the knee to 5 degrees and then rotate his or her body and knee internally and externally three times. This is repeated with the knee at 20 degrees of flexion. A test is positive if the patient has joint line pain or a sense of locking or catching in the knee. The diagnostic test of choice is MRI of the knee, although standard knee radiographs should be included. It is important to note that the increased vascularity of the meniscus in the pediatric population often causes increased signal changes on MRI that can be confused with a tear. Therefore, an MRI diagnosis of a meniscal tear in a young athlete needs to be correlated with the patient’s clinical symptoms and examination.

**Treatment**

Treatment of these injuries is typically surgical because of the limited ability of the meniscus to heal without surgical intervention. Nonoperative management can be considered if the tear is minor and symptoms are minimal. Surgery can entail repairing the tear or removing the torn portion of the meniscus. Typically, every attempt is made to preserve the meniscal tissue in young athletes because of their favorable healing rates and the long-term concern over the development of arthritis in meniscal deficient patients. Meniscectomy (removal of torn tissue) patients can often return to sports 3–6 weeks after surgery. Meniscal repair patients require a period of 6 weeks of crutch protection followed by physical therapy. Return to sport after a repair is typically 3–4 months.

4. Medial & Lateral Collateral Ligament Injuries

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Pain on the medial or lateral portion of the knee.
- Tenderness along the ligament.
- Positive valgus or varus stress test at 0 and 30 degrees.

The medial and lateral collateral ligaments are positioned along either side of the knee and act to stabilize the knee during varus and valgus stress. Medial injuries occur either with a blow to the lateral aspect of the knee, as seen in a football tackle, or with a noncontact rotational stress.

**Clinical Findings**

The athlete may feel a pop or pain sensation along the medial or lateral aspect of the knee. The examination reveals a mild effusion and tenderness medially or laterally along the course of the ligament. A varus stress test performed in 20–30 degrees of flexion reproduces pain and possibly instability in medial collateral ligament injuries. A varus stress test performed in 20–30 degrees of flexion reproduces pain and possible instability in lateral collateral ligament injuries. Medial collateral ligament (MCL) and lateral collateral ligament (LCL) injuries are graded on a scale of 1–3. Grade 1 injury represents a stretching injury. Grade 2 injury involves partial disruption of the ligament. Grade 3 injury is a complete disruption of the ligament. Radiographs are useful, especially in the skeletally immature athlete, to look for distal femoral or proximal tibial bone injury. MRI scans are used if grade 3 injury or concomitant intra-articular derangement is suspected.

**Treatment**

Treatment is almost always conservative. Initial injuries should be iced and elevated. A protective brace is worn
and full knee motion in the brace can be permitted within a few days. Weight bearing is allowed and a strengthening program can be started. The athlete should use the brace until pain and range of motion have improved. The use of a functional brace is often required when a player returns to competition. Bracing is temporary until the ligament heals completely and the athlete has no subjective feelings of instability. Return to sports is variable and is dependent on the severity of the tear and other associated injuries. Most isolated, low-grade MCL injuries can return to play in 3–5 weeks.

5. Anterior Cruciate Ligament Injuries

The anterior cruciate ligament (ACL) consists of two bundles that prevent anterior subluxation and rotation of the tibia. Most ACL injuries are noncontact and occur with deceleration, twisting, and cutting motions. ACL injuries can also occur with knee hyperextension or from a direct blow to the knee—typically on the lateral side—which causes an extreme valgus stress with both ACL and MCL disruption.

Clinical Findings

The athlete often reports hearing or feeling a “pop” followed by swelling that occurs within hours of the injury. Evaluation of the knee begins with examination of the uninjured knee. The Lachman test provides the most accurate information about knee stability in relation to the ACL. The Lachman test is performed by holding the knee in 30 degrees of flexion while supporting the tibia and femur. The proximal tibia is pulled anteriorly, and the degree of excursion and the firmness of the endpoint are assessed and compared to the contralateral side. All other structures of the knee should be examined to rule out concomitant injuries. Imaging of the knee includes plain radiographs and an MRI scan. In skeletally immature athletes, a tibial spine avulsion is frequently seen on radiographs rather than a midsubstance ACL tear.

Treatment

Initial treatment focuses on controlling swelling and pain. Structured physical therapy can be instituted early to assist in regaining range of motion and strength. Conservative treatment includes bracing, strengthening, and restricting physical activity. Knee braces enhance proprioception and control terminal extension. Conservative management can be complicated by continued instability and damage to meniscal and articular cartilage.

Surgical reconstruction is typically indicated for young athletes in cutting sports and is also required for persistent instability. Surgery can be performed 2–6 weeks following the injury if the swelling and motion of the knee have improved. Recent advances in surgical treatment of the skeletally immature athlete have been helpful in dealing with the complicated management of young athletes with ACL tears. Rehabilitation of the knee starts immediately after surgery. A structured ACL physical therapy protocol is initiated with the goals of building strength, muscle reeducation, endurance, agility, and coordination. Return to cutting and pivoting sports can be achieved by 6 to 9 months after surgery if certain criteria are met, although many young athletes will need 12 months or more before they are ready to return to sports.

6. Posterior Cruciate Ligament Injuries

The posterior cruciate ligament (PCL) runs from the medial femoral condyle to the posterior tibial plateau and has two bundles. Its main function is to prevent posterior tibial subluxation. Injury to the PCL is uncommon; it occurs when the individual falls on a flexed knee with the ankle in plantarflexion or with forced hyperflexion of the knee. The most common sports in which PCL injuries are sustained are football and hockey.

Clinical Findings

The athlete presents with swelling and pain in the posterior and lateral knee. The examination begins with the uninjured knee and proceeds to the injured side. Confirmatory testing includes the posterior drawer test, performed with the patient supine, the knee flexed to 90 degrees, and the foot stabilized. Grading is based on the amount of translation. Grade 1 (mild) is up to 5 mm, grade 2 (moderate) is 5–10 mm, and grade 3 (severe) is more than 10 mm. Grade 3 injuries are typically indicative that another ligament is injured in addition to the PCL and should alert the provider...
to an associated injury. Diagnostic imaging includes plain radiographs and MRI scan.

**Treatment**

Isolated PCL injuries are almost universally treated nonoperatively. The exception is bony avulsions of the PCL off the femur or tibia. Generally, surgical fixation is recommended for these injuries. Ligamentous PCL injuries in isolation are remarkably well tolerated in athletes and can be treated with bracing and a progressive rehabilitation program. PCL injuries with injury to other structures are complex and often require surgical stabilization. Surgical stabilization of these injuries is complicated, and return to sports at the previous level is uncertain after combined injuries that involve the PCL.

**FOOT & ANKLE INJURIES**

Injuries in the lower leg, ankle, and foot are common in pediatric athletes. The types of injuries sustained typically depend on the age group. Young children tend to have diaphyseal injuries, in contrast to older children in rapid growth, who tend to have epiphyseal and apophyseal injuries. Skeletally mature adolescents are prone to adult-pattern ligamentous injury. Although fractures of the ankle are possible with inversion and eversion mechanisms, the most common acute injury involving the ankle is the lateral ankle sprain.

1. **Ankle Sprain**

   **ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

   • Mechanism is usually inversion and plantarflexion.
   • Swelling and pain in the ankle over the ligament.
   • Bruising over the ankle.

   When a ligament is overloaded, tearing occurs. These injuries are graded on a scale of 1–3. Grade 1 injury is a stretch without instability; grade 2 is a partial tear with some instability; and grade 3 is a total disruption of the ligament with instability of the joint. The ankle has three lateral ligaments (anterior talofibular, calcaneofibular, and posterior talofibular) and a medial deltoid ligament. Inversion of the foot generally damages the anterior talofibular ligament, whereas eversion injures the deltoid ligament. Lateral ankle sprains are far more common than medial ankle sprains because the deltoid ligament is stronger mechanically than the lateral ligaments. However, medial ankle sprains may have more severe complications, including syndesmotic tearing and instability of the ankle joint requiring surgical stabilization. High ankle sprains involve injury to the tibiofibular syndesmosis, a movable connection in which the adjacent tibia and fibula bones are bound together by ligamentous structures. The syndesmosis supports the integrity of the ankle mortise joint. The ankle mortise is defined as the bony arc formed by the tibial plafond, the medial and lateral malleoli, and the roof of the talus. The mortise provides the wide range of flexibility and motion of the ankle, but its injury causes instability and pain. Syndesmotic injuries do not typically require surgery but do involve longer healing times than low-grade medial or lateral ankle sprains.

**Clinical Findings**

Physical examination often reveals swelling, bruising, and pain. Diagnostic testing should be done when a bony injury is suspected. Obtaining radiographs is especially important when evaluating skeletally immature athletes who are more prone to growth plate injury. Medial ankle swelling, tenderness, and bruising warrant ankle three-view radiographs (AP, lateral, mortise) to evaluate asymmetry and instability of the ankle mortise.

The adult Ottawa Ankle Rules are used to determine whether obtaining x-rays are necessary and appear to be reliable in patients older than 5 years. Tenderness over the malleoli, tenderness beyond ligament attachments, and excessive swelling are additional reasons to obtain radiographs in young athletes.

**Differential Diagnosis**

Other injuries to consider include injuries to the fifth metatarsal, which can occur with an inversion mechanism. In this injury, the athlete presents with localized swelling and tenderness over the base of the fifth metatarsal. Fractures at the base of the fifth metatarsal can be divided into avulsion, Jones, and diaphyseal fractures. High-ankle sprains (a.k.a. syndesmotic injuries) occur most commonly with dorsiflexion and external rotation. Radiographs are required and the syndesmotic squeeze test and Kleiger test (external rotation of the foot in dorsiflexion) are positive. Fractures of the tibial epiphysis, malleoli, fibula, talar dome, or calcaneus may also mimic an ankle sprain.

**Treatment**

Appropriate treatment of ligamentous ankle injuries is imperative to ensure full recovery and should begin immediately after the injury. Fractures and instability of the ankle
mortise require immediate orthopedic surgical referral. Nonoperative management is typical of the vast majority of ankle sprains. Phase 1 care involves immediate compressive wrapping and icing to control swelling and inflammation. Protected weight bearing is encouraged as tolerated in the early phase of rehabilitation. Severe ankle sprains may benefit from a short period of treatment in a lower leg walking boot or cast. Phase 2 begins when the athlete can ambulate without pain. Supervised physical therapy prescription may be beneficial. During this time, ankle range of motion is emphasized, along with isometric contractions of the ankle dorsiflexors. Once 90% of strength has returned, active isotonic (eccentric and concentric exercises) and isokinetic exercises can be added. Phase 3 is designed to increase strength, improve proprioception, and add ballistic activity (more complex movement patterns), as well as sport-specific agility and function. The “foot alphabet” and “balance board” are excellent methods to improve ankle range of motion and proprioception. To restore range of motion, the patient is asked to actively move the ankle by drawing letters of the alphabet with the toes. To restore proprioception, the ability to maintain proper balance and control, balance exercises are performed on a balance board (or wobble board). This could also be done by having the patient stand on one leg while playing catch with a ball. This program can be effective in returning athletes to activity within a few weeks, although up to 6 weeks may be required for return to full activity. The athlete should wear a protective brace for 3–4 months, continue phase 3 home exercises, and ice after exercising.

2. Sever Disease

TYPICAL FEATURES

- Activity-related heel pain in preadolescents.
- Pain localized to the calcaneal apophysis and Achilles insertion.
- Positive calcaneal squeeze test.

Sever disease, or calcaneal apophysitis, occurs in athletes aged 8–12 years who are typically involved in high-impact activities, such as gymnastics and soccer. Causes include overuse, improper footwear, and tightness in the calf muscle and Achilles tendon. Pain occurs about the heel and at the point of muscle tendon insertion onto the growth center of the calcaneus. The athlete presents with activity-related heel pain and examination reveals focal tenderness over the calcaneal apophysis. Tenderness created by pressing forcefully on the lateral and medial heel constitutes a positive “calcaneal squeeze test.”

Treatment is symptomatic and consists of reassurance and education, relative rest, heel cord stretching, eccentric calf strengthening, ice massage, heel cups, NSAIDs for pain control, and progression to activity as tolerated based on pain level. Activity restriction is not required. Heel cups are rubber or gel infused shoe inserts that provide heel lift and cushion to decrease both tension and impact on the calcaneal apophysis. Refractory cases may benefit from brief immobilization and partial or non-weight bearing in a walking boot or cast followed by supervised physical therapy.

3. Plantar Fasciitis

Plantar fasciitis is a common problem that manifests as heel pain in the adolescent or older athlete. It typically occurs in runners who log more than 30 miles per week and in athletes who have tight Achilles tendons or wear poorly fitting shoes. It is also common in people with cavus feet and in those who are overweight. The pain is worse upon first standing up in the morning and taking a few steps. Differential diagnosis includes navicular or calcaneal stress fracture. A bone spur is often found on examination. Treatment involves local massage, stretching of the gastrocnemius-soleus-Achilles complex, NSAIDs, arch supports, and local steroid injections. Runners may need to cut back on their weekly mileage until these measures eliminate pain.

incidence of eye injuries. Proper protective padding should be identified and used, including chest pads for catchers; shin guards in soccer; shoulder, arm, chest, and leg padding in hockey; and wrist and elbow protectors in skating. Other primary prevention strategies should also be addressed by coaches, parents, and physicians in order to ensure the safety of children participating in sports. These include inspecting playing fields for potential hazards, adapting rules to the developmental level of the participants, and matching opponents equally in skill level and size.

The use of the preparticipation history and physical examination can identify potential problems and allow for prevention and early intervention. Proper training techniques reduce injuries by encouraging flexibility, promoting endurance, and teaching correct biomechanics. Sports education reinforces the concepts of fitness and a healthy lifestyle along with sport-specific training. Early identification of an injury allows the athlete to modify techniques and avoid micro- and macrotrauma. Once an injury has occurred, it needs to be identified properly and appropriate measures used to minimize morbidity. Rehabilitation of the injury starts as soon as it has been identified. Early and appropriate care offers the athlete an optimal chance for full recovery and return to full participation.

Rehabilitation medicine is the multispecialty discipline involved in diagnosis and therapy of individuals with congenital and acquired disabilities. The goals of rehabilitation medicine are to maximize functional capabilities and improve quality of life. Disabilities are described using the World Health Organization’s International Classification of Function, Health, and Disability. Three aspects are evaluated in every patient: (1) the impact of the disability on body structure and function, (2) the impact of the disability on activity and participation in society, and (3) the environmental factors with an impact on the individual’s function. These three areas are the common framework for discussion of a disabling condition and its therapy.

**PEDIATRIC BRAIN INJURY**

<table>
<thead>
<tr>
<th>ESSENTIALS OF DIAGNOSIS &amp; TYPICAL FEATURES</th>
</tr>
</thead>
<tbody>
<tr>
<td>► Severe head injury: Glasgow coma scale (GCS) of &lt; 9.</td>
</tr>
</tbody>
</table>

Various estimates indicate that there are up to 500,000 pediatric traumatic brain injuries in the United States every year, resulting in 37,000–50,000 hospitalizations. Mortality rates vary significantly by region (relative risk 1.19–4.2 nationally), but, overall, pediatric brain injuries result in 2000–3000 deaths annually. The cost of these injuries is significant, particularly when also considering that survivors of pediatric brain injury may have long-term deficits with lifetime needs.

**Pathogenesis**

Brain injury is classically divided into two categories based upon the timing of the pathologic findings: primary and secondary injury.

Primary injury occurs at the time of trauma, causing focal and diffuse mechanical damage to both neurons and glia as well as the vasculature and is typically irreversible. Focal damage includes skull fracture, parenchymal bruising or contusion, extraparenchymal or intraparenchymal hemorrhage, blood clots, tearing of blood vessels, or penetrating injury. Diffuse damage includes diffuse axonal injury and edema. Consequences of primary injury, either focal or diffuse, include cellular disruption with release of excitatory amino acids, opiate peptides, and inflammatory cytokines.

Secondary injury is the loss of cellular function accompanying primary injury that results in loss of cerebrovascular regulation, altered cellular homeostasis, or cell death and functional dysregulation. Mitochondrial dysfunction due to dysregulation of Ca++ and other cations and anions leads to depletion of ATP to drive homeostatic cellular pumps. This leads to oxidation of cellular DNA, protein and lipids causing among other things cell death. These multiple mechanisms can also lead to increased extracellular glutamate resulting in excess depolarization further stressing compromised cells. A primary injury can initiate the processes of secondary programmed cell death (apoptosis), which further exacerbates the primary injury. Secondary injury may develop hours or days after the initial insult. It appears to be precipitated by elevated intracranial pressure, cerebral edema, and release of neurochemical mediators. Current treatment paradigms are focused on treating and preventing secondary injury.
Clinical Findings

Classification & Assessment of Injury Severity

Traumatic brain injury is usually categorized as open or closed. *Open* injuries are the result of penetration of the skull by missile or sharp object or deformation of the skull with exposure of the underlying intracranial tissues. *Closed* injuries are the result of blunt trauma to the head, which causes movement (intracranial acceleration or deceleration and rotational forces) and compression of brain tissue. Brain contusions are referred to as *coup* occurring at the site of injury) or *contra-coup* (occurring on the side of the brain opposite the injury). Rating the severity of injury and eventual outcomes is important in medical management. Included below are the two most commonly used scales relevant to clinical care of these injuries in rehabilitation medicine.

A. Glasgow Coma Scale

The GCS is the most commonly used system to assess the depth and duration of impaired consciousness in the acute setting. The score is derived from three areas of evaluation: motor responsiveness (maximum score 6), verbal performance (maximum score 5), and eye opening to stimuli (maximum score 6). The scale has been modified for use in infants and children younger than 5 years, allowing for their lack of verbal responsiveness and understanding. Cumulative scores define injury as mild (13–15), moderate (9–12), and severe (≤ 8). The concept of posttraumatic amnesia is used to gauge severity of injury and is an adjunct to the GCS. Posttraumatic amnesia is the period after an injury during which new memory cannot be incorporated and the person appears confused or disoriented. Amnesia can be retrograde, anterograde, or both.

B. Rancho Los Amigos Levels of Cognitive Function

The Rancho Los Amigos Levels of Cognitive Function (LCFS or “Rancho”) is used to gauge the overall severity of cognitive deficit and can be used serially during recovery as a rough gauge of improvement. The scale has 10 levels of functioning ranging from “no response” to “purposeful, appropriate.”

Common Sequelae of Brain Injury

Depending on the severity of brain injury, there may be deficits in cognition and behavior, as well as physical impairments. Injuries can also produce changes in sensory and motor function, emotional stability, social behavior, speed of mental processing, memory, speech, and language. The consequences of mild brain injuries may be difficult to discern. Small intraparenchymal injuries, easily identified by computed tomographic (CT) or magnetic resonance imaging (MRI) scans, may not cause obvious signs or symptoms. The following are common problems associated with brain injury.

A. Seizures

Seizures occurring in the first 24 hours after injury are referred to as *immediate seizures*. Those occurring during the first week are *early seizures*, and those starting more than 1 week after injury are referred to as *late seizures*. Seizure prophylaxis with medications is recommended in the first week after brain injury in children at high risk for seizures and in very young children. Seizure prophylaxis is also recommended for 1 week after any penetrating brain trauma. Seizure prophylaxis is probably not effective for prevention of late-onset seizures; these may require long-term treatment.

B. Neuromotor Deficits/Movement Disorders

Neuromotor deficits after brain injury include movement disorders, spasticity, paralysis, and weakness. The type of disorder will be influenced by the areas damaged. The most common movement disorders are tremors and dystonias. These deficits can result in impaired ambulation, coordination, impaired ability to use upper extremities, and speech problems. Physical therapy is the primary means of treating these problems.

C. Communication Disorders

Language and communication disorders are common. Aphasia, difficulty in understanding and producing written and spoken language, is categorized as fluent, nonfluent, or global. Individuals with fluent aphasia or Wernicke-type disorder can produce speech, but have little content associated. The nonfluent aphasias or Broca’s type have a paucity of speech and may have word finding difficulties. Global aphasias have extensive injuries and the most severe language disorders.

D. Paroxysmal Sympathetic Hyperactivity

Severe brain injuries may be associated with excessive sympathetic outflow and results in a constellation of symptoms known as paroxysmal sympathetic hyperactivity (PSH). Symptoms of PSH are tachycardia, tachypnea, sweating, hyperthermia, hypertension, agitation, and posturing. Common medications used to treat PSH include dopamine agonists (eg, bromocriptine), β-blockers (eg, propranolol), and α-agonists (eg, clonidine).

E. Cognitive and Behavioral Deficits

After brain injury, cognitive and behavioral deficits are a frequent occurrence. Cognitive disorders depend on the location and severity of the injury. Damage to the frontal
lobes can disrupt executive function along with initiation delays. Neuropsychiatric sequelae are common, and depression, anxiety disorders, and posttraumatic stress disorders (PTSD) are present in one-third of those injured. Testing by a neuropsychologist may help to identify problem areas allowing for development of accommodations in school and use of behavioral strategies.

F. Hypothalamic-Pituitary-Adrenal Axis Dysfunction

Dysfunction of the hypothalamic-pituitary-adrenal axis is common after head injury. The syndrome of inappropriate secretion of antidiuretic hormone (SIADH) and diabetes insipidus (DI) from a posterior pituitary injury can result in significant electrolyte and osmolality imbalance. Amenorrhea that typically resolves spontaneously is common in females. Injury near the onset of puberty can complicate normal development, and endocrine status should be monitored closely.

G. Cranial Nerve Injuries

The sensory and motor components of the cranial nerves are often damaged, resulting in a wide variety of deficits not centrally mediated. The most commonly injured nerves are I, IV, VII, and VIII. Hyposmia or anosmia (cranial nerve I) can occur if the shearing forces at the cribriform plate disrupt the afferent olfactory nerves. Injury to cranial nerves IV (trochlear) is common as it has the longest intracranial length. Superior oblique injuries typically cause a head tilt and vertical diplopia. Facial nerve injuries (cranial nerve VII) are common especially with temporal bone fractures. This impacts the ability to use the facial muscles, causes dryness in the eye and salivary glands along with decreasing taste in the anterior part of the tongue. The cochlear nerve (VIII) is also frequently damaged in temporal bone fractures and can result in vertigo and dizziness.

Developmental Considerations

Much of what we know of traumatic brain injury is based on adult experience. The confounding effects of age and the etiologies unique to the pediatric population (eg, child abuse) make care of the pediatric head-injured patient very complex.

The assumption that younger children will fare better than older children or adults after a brain injury is a myth. The fact that in a child a significant amount of development and synaptic reorganization has yet to occur does not guarantee an improved chance for functional recovery. Indeed, disruption of developmental processes, especially in very young infants or neonates, may be catastrophic. These processes often cannot be recapitulated.

The mechanism of injury plays an important role in determining the severity of brain injury in very young children. Mechanisms associated with non-accidental injury such as shaking often result in global diffuse damage. The weak neck musculature, large head-body mass ratio, immature blood-brain barrier, and high intracranial fluid–brain mass ratio all contribute to widespread damage.

During puberty, major hormonal changes have an impact on the outcome of brain injury. Behavioral problems may be pronounced in brain-injured adolescents. Precocious puberty and precocious development of sexual activity may occur in preadolescents and should be carefully monitored.

Careful consideration should be given to the developmental progress of the brain-injured child and adolescent. Delays can be anticipated after moderate and severe brain injuries related to abnormalities of cognition and behavior. Educational programs should include an individualized educational program (IEP) to support the child with significant remediation and assistance during their school years. Programs should also include a 504 plan (Section 504 of the Rehabilitation Act and the Americans with Disabilities Act). The 504 plan identifies the accommodations necessary in regular school settings for students with lesser disabilities so that they may be educated in a setting with their peers.

Treatment

The primary goal of rehabilitation after childhood brain injury is to maximize functional independence. Rehabilitative care can be divided into three phases: acute, sub-acute, and long term. The acute and sub-acute phases typically occur in the inpatient setting while the long-term phase is an outpatient endeavor.

A. Acute Care

Therapy in the acute phase consists mainly of medical, surgical, and pharmacologic measures to decrease brain edema, treat increased intracranial pressure, and normalize laboratory values. Nutrition is essential in the healing process and either parenteral nutrition or supplemental enteral feedings are employed. Current research suggests that transitioning to enteral nutrition (eg, nasogastric tube feeding) as soon as possible after brain injury is associated with improved outcomes. Placement of a gastrostomy tube for supplemental enteral feeding is often performed in patients with severe brain injuries when recovery will be protracted and swallowing function is inadequate for safe oral feeding.

B. Sub-Acute Care

Therapy in the sub-acute phase is characterized by early, intensive participation in rehabilitative therapies promoting functional recovery. Treatment should be planned after consultation with physical therapy, occupational therapy, speech-language specialists, and neuropsychologists. Nursing staff members are a primary interface with the patient and often serve as educators for family-directed care. Pharmacological approaches may be used to enhance arousal and focus in patients with traumatic brain injury to enable them...
to more fully participate in therapies or to deal with other sub-acute sequelae such as agitation. Most children and adolescents with brain injuries can be discharged home to continue with treatment on an outpatient basis.

C. Long-Term Care

Long-term follow-up starts immediately after discharge. Annual multidisciplinary evaluation, including neuropsychological testing is important as the child approaches school age so strategies to deal with noted deficits can be implemented to improve outcomes within the educational environment.

Medication is often required for cognitive and behavioral issues. Attention deficit and fatigue may be amenable to treatment with stimulants such as methylphenidate and modafinil. Dopaminergic agents such as amantadine, levodopa, and bромокриптин can be useful in improving cognition, processing speed, and agitation. Antidepressants such as selective serotonin reuptake inhibitors can be helpful in treating depression and mood lability. Anticonvulsants can be used as mood stabilizers and in treating agitation and aggression. Tegretol and valproic acid are typical agents for this purpose.

Attention and arousal can also be successfully addressed by utilizing behavioral techniques to reinforce desired behaviors and by identifying environmental situations to facilitate success. Gains made in the behavioral realm often have a positive impact on therapies designed to address physical issues.

Prognosis & Outcomes

Directly after brain injury, poor pupillary reactivity, low blood pH, absence of deep tendon reflexes, and low GCS all correlate with poor outcome. Coalescing lesions noted on imaging and increased depth and duration of coma suggest more severe injury and poor functional recovery. Children younger than 1 year tend to have worse outcomes.

Functional outcome assessment is important for judging the efficacy of rehabilitation therapy. Global multidomain measures (eg, FIM/WeeFIM) are used to provide a functional “snapshot in time” of select functions—motor function and mobility, self-care, cognition, socialization, and communication. Simpler, single-domain, functional assessment tools such as the Glasgow Outcome Scale (GOS) and its pediatric cousin, the Kings Outcome Scale for Childhood Head Injury (KOSCHI), may also be of use. The National Institute of Neurological Disorders & Stroke (NINDS) is coordinating an effort to validate and promote the use of “common data elements” for evaluating outcomes of brain injury (www.commondataelements.ninds.nih.gov). The goal of this effort is to promote the use of common measures that will facilitate comparison of results across studies and generalizable conclusions.

Outcome associated with mild brain injury is often quite favorable. Most patients recover normal function within a short time. A small percentage develop persistent problems such as chronic headache, poor focusing ability, altered memory, and vestibular abnormalities which may last for many weeks or months. Differentiating between musculoskeletal and central nervous system (CNS) etiologies of persistent symptoms such as headache is important and can influence prognosis and care planning.

In children, recovery may not be fully achieved for many months or years after the initial injury. The impact of the injury on developmental processes and its future consequences are difficult to predict. Long-term follow-up is required, particularly as the child approaches school age.

www.commondataelements.ninds.nih.gov

SPINAL CORD INJURY

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

Spinal cord injury (SCI) is an alteration in normal motor, sensory, or autonomic function secondary to spinal insult.

Characterized as either complete (total loss of function) or incomplete (some preservation of function below the level of lesion).

Epidemiologic studies of SCI suggest that there will be about 10,000 new injuries per year and that 20% will be in those younger than age 20 years. Motor vehicle accidents are the leading cause of SCI in all ages. Falls are common causes in young children. The phenomenon of SCI without radiologic abnormality (SCIWORA) can be present in 20%–40% of young children. Children from birth to 2 years tend to have high-level injuries to the cervical spine because of anatomical features of their spine. The facets tend...
to be shallower and oriented horizontally, and the boney spine is more flexible than the spinal cord. In addition, the head is disproportionately large and the neck muscles are weak.

**Clinical Findings**

**A. Classification and Assessment of Injury Severity**

SCI is classified using the International Standards for Neurological Classification of Spinal Cord Injury (ISNCSCI), formerly known as the American Spinal Injury Association (ASIA) classification system.

This classification evaluates motor and sensory function, defines the neurologic level of the injury, and assesses the completeness (level of motor or sensory sparing) of the deficit. The 72-hour examination is used in predicting recovery. A complete lesion identified on examination at 72 hours predicts a poor recovery potential. The ISNCSCI classification is as follows:

1. **Class A** is a complete SCI, with no motor or sensory function in the lowest sacral segments.
2. **Class B** is an incomplete injury, with preserved sensory function but no motor function in the sacral segments.
3. **Class C** is an incomplete lesion in which the strength of more than 50% of key muscles below the injury level is graded less than 3/5 on manual muscle testing.
4. **Class D** is an incomplete lesion in which the strength of more than 50% of key muscles below the injury level is graded greater than 3/5 on manual muscle testing.
5. **Class E** is an injury in which full motor and sensory function is preserved.

**B. Clinical Patterns of Spinal Cord Injury**

1. **Brown-Séquard injury**—The cord is hemisected causing motor paralysis, loss of proprioception and vibration on the ipsilateral side, and loss of pain and temperature on the contralateral side.
2. **Central cord syndrome**—Injury is to the central part of the cord and results in greater weakness in the arms than the legs.
3. **Anterior cord syndrome**—Disruption of the anterior spinal artery causes motor deficits and loss of pain and temperature sensation. Proprioception and fine touch is spared.
4. **Conus medullaris syndrome**—Injury or tumor of the conus, the lower conical shaped end of the spinal cord, can cause minimal motor impairment but significant sensory, bowel, and bladder abnormalities.
5. **Cauda equina syndrome**—Injury to the nerve roots produces flaccid bilateral weakness in the legs, sensory abnormalities in the perineum, and lower motor neuron bowel and bladder dysfunction.

**C. Imaging**

The diagnosis and anatomic description of SCI is made mainly through imaging techniques. Initial studies should include radiographs of the entire spine (including cervical spine) and special studies for boney structures. MRI imaging is required to evaluate soft tissues. CT scans, including three-dimensional reconstructions, may be used to further define the injured elements.

**Treatment**

**A. Initial Management**

The two primary precepts of SCI treatment are early identification and immediate stabilization of the spine. The approach used to stabilize the spine is determined by the type of injury, location of injury, and underlying condition of the spinal cord. Stabilizing the spine may prevent further damage to the spinal cord. External traction devices such as halo traction and orthotics are often used. Some injuries require internal stabilization. The benefit of methylprednisolone administration in acute SCI has recently come into question. Based on the ongoing controversy regarding efficacy and outcomes, steroids remain an option, but their administration is not considered standard of care.

**B. Functional Expectations After Spinal Cord Injury**

The lesions associated with SCI have a predictable impact on motor and sensory function. It is helpful to understand these concepts when discussing functional expectations with patients and parents (Table 28–1).

**C. Special Clinical Problems Associated With Spinal Cord Injury**

1. **Autonomic hyperreflexia or dysreflexia**—This condition occurs in spinal injuries above the T6 level. Noxious stimuli in the injured patient cause sympathetic vasoconstriction below the level of injury. Vasoconstriction produces hypertension and then a compensatory, vagal-mediated bradycardia. Symptoms include hypertension, bradycardia, headaches, and diaphoresis. This response may be severe enough to be life threatening. Treatment requires identification and relief of the underlying noxious stimulus. Bowel, bladder, and skin problems are the most common stimuli. The patient should be placed in an upright position and antihypertensive medication used if conservative measures fail.

2. **Hypercalcemia**—Hypercalcemia, in response to immobilization, often occurs in male adolescents within the first 2 months of becoming paraplegic or tetraplegic. Patients complain of abdominal pain and malaise. Behavioral problems may occur. Initial treatment is focused on hydration.
and forced diuresis using fluids and furosemide to increase urinary excretion of calcium. In severe cases, especially in older children, calcitonin and etidronate may be required.

3. Thermoregulation problems—These problems are common in higher level injuries and usually result in a poikilothermic state where body temperature changes with that of the environment. The ability to vasoconstrict and vasodilate below the injury level is impaired. The person with an SCI above T6 is particularly susceptible to environmental temperature and is at risk for hypothermia and hyperthermia.

4. Deep vein thrombosis—Thrombosis is a common complication of SCI, especially in postpubescent children. Deep vein thrombosis should be suspected in children with any unilateral extremity swelling, palpable cords in the calf muscles, fevers, erythema, or leg pain. Diagnosis is confirmed by Doppler ultrasound, and full evaluation may require spiral CT scan or ventilation-perfusion scan if pulmonary embolus is suspected. Preventative measures include elastic stockings and compression devices. Anticoagulation prophylaxis may be required using medications such as low-molecular-weight heparins (eg, enoxaparin).

5. Heterotopic ossification—This complication occurs in both spinal cord and traumatic brain injuries. Ectopic calcium deposits usually appear around joints in the first 6 months after injury. They may cause swelling, decreased range of motion, pain with motion, palpable firm masses, fever, elevated sedimentation rate, and abnormal triple phase bone scan. Nonsteroidal anti-inflammatory drugs or bisphosphonates such as Etidronate should be started at the time of diagnosis. Surgical removal of ectopic deposits is controversial and usually performed only in cases of extreme loss of motion, pressure sores, or severe pain.

BRACHIAL PLEXUS LESIONS & TYPICAL FEATURES

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Upper trunk (C5 and C6) is the most common area injured and results in the classic Erb palsy.
- Injury to the lower trunk (C7–T1) produces a Klumpke palsy.
- Pan plexus lesion involves all roots.

Pathogenesis

Brachial plexus lesions associated with delivery are related to traction applied to the nerves and is often associated with shoulder dystocia. The nerve injury can range from simple neuropaquia (stretch) to complete avulsion. Acquired brachial plexus injuries from sports, surgery, and accidents also have a mechanism which stretches or injures the plexus.
CHAPTER 28

Prevention

Identification of factors associated with shoulder dystocia, such as macrosomia, or proper positioning during surgical procedures to decrease traction on the brachial plexus may reduce the incidence of these lesions.

Clinical Findings

Erb palsy has been described as the “waiter’s tip posture” and is characterized by shoulder weakness with internal rotation and adduction of the upper arm. The elbow is extended and the wrist flexed. There is good preservation of hand function. Klumpke palsy is characterized by good shoulder function but decreased or absent hand function. Brachial plexus injuries may also cause a Horner syndrome (unilateral miosis, ptosis, and facial anhidrosis) due to disruption of cervical sympathetic nerves. The physical examination should include inspection of the humerus and clavicle for fractures. There may be injuries of the phrenic and facial nerves. The diagnosis of a brachial plexus lesion should be based on the history and clinical examination. Diagnostic testing helps confirm, localize, and classify the lesion. Electromyography is helpful 3–4 weeks after the injury. This test not only is used diagnostically but also can track recovery. MRI, myelography, and CT scan can help to locate the lesion and determine its extent.

Complications

The development of complications reflects the degree of nerve recovery. Severe injuries are at risk for shoulder contractures, muscle atrophy, osseous deformities, functional deficits, pain, and maladapted postures.

Treatment & Prognosis

The treatment for brachial plexus lesions will depend on the severity of the lesion. Many will heal on their own and no interventions are needed. For persistent injuries, physical/occupational therapy is the major treatment and includes stretching, bracing, strengthening, electrical stimulation, and functional training. Primary surgery to the nerves of the plexus is indicated for children who have no spontaneous recovery of biceps function by 6–9 months. Secondary procedures to maximize function include muscle transfers and orthopedic interventions.

Many factors are used to predict recovery. The anatomic location of the lesion impacts recovery, as upper trunk lesions do better than lower trunk lesions. If a Horner syndrome is present, these injuries always have a poor recovery. Children in whom antigravity function returns within 2 months of injury will usually have a good recovery of function. If antigravity function is delayed until 6 months, recovery will probably be limited. If antigravity function is absent at 6–9 months, there will be no recovery of function and surgery should be considered.

COMMON REHABILITATION PROBLEMS

Neurogenic bladder may be caused by trauma or disease affecting central or peripheral connections and can be classified depending on the type of dysfunction.

Neurogenic bowel may be caused by upper or lower motor neuron damage with loss of sensation and sphincter control, with or without reflexive bowel activity depending on injury.

Spasticity, a velocity dependent increase in tone and loss of isolated muscle function, is commonly graded using the Ashworth Scale.

1. Neurogenic Bladder

During the first year of life, the bladder is a reflex-driven system that empties spontaneously. After the first year, control begins to develop and most children achieve continence by age 5 years. Children with damage to the central or peripheral nervous system may develop a neurogenic bladder. The diagnosis of neurogenic bladder requires a complete history and physical examination and is usually classified as follows:

1. **Uninhibited** neurogenic bladder occurs after upper motor neuron injuries at the level of the brain or spinal cord that result in failure to inhibit detrusor contractions. This results in a hyperreflexive voiding pattern.

2. **Reflex** neurogenic bladder results from damage to the sensory and motor nerves above the S3 and S4 level. The bladder empties reflexively but coordination may not be present and dyssynergia (contraction of the bladder musculature against a closed sphincter) can occur. Increased intravesicular pressure and vesicourethral reflux may be consequences of dyssynergia.

3. **Autonomic** neurogenic bladder is a flaccid bladder and is associated with lower motor neuron damage. Bladder volumes are usually increased and overflow incontinence can occur.
4. **Motor paralytic** neurogenic bladder results from injury to the motor nerves of the S2–S4 roots. Sensation is intact but there is motor dysfunction. The child has the sensation to void but has difficulty with the voluntary contractions.

5. **Sensory paralytic** neurogenic bladder results when sensory roots are disrupted. Affected patients do not have sensation of the full bladder but are able to initiate voiding.

The type of neurologic damage should be identified as this will help to predict anticipated voiding issues. The upper tracts should be assessed using ultrasound, intravenous pyelogram, or renogram (isotope) studies. Lower tract testing includes urinalysis, postvoid residuals, urodynamics, cystography, and cystoscopy.

### Treatment

Treatment is geared to the type of bladder dysfunction. The simplest methods, such as timed voiding, can be effective for children with uninhibited bladders. In this technique, children are reminded verbally or use a cueing device (watch with a timer) to void every 2–3 hours before bladder capacity is reached. The Credé and Valsalva maneuvers are used in patients with an autonomous bladder to assist in draining a flaccid bladder. There is a risk of provoking vesicoureteral reflux by increasing intravesical pressure during these maneuvers which should never be used in a patient with a reflex neurogenic bladder.

Medications are often employed to treat neurogenic bladder. Anticholinergics are commonly used to reduce detrusor contractions, decrease the sense of urgency, and increase bladder capacity. Medications include oxybutynin, tolterodine, and hyoscyamine. The side effects of these medications include sleepiness, nausea, and constipation. Absorbent pads and diapers, external catheters, indwelling catheters, and intermittent catheterization are also effective. A young child with a high-pressure bladder is at particular risk for reflux and may need medication, intermittent catheterization, or vesicostomy to prevent hydrostatic renal damage and infection. An older child may require reconstructive bladder surgery (bladder augmentation) to increase the capacity of the bladder or an intestinal conduit from bladder to skin surface (Mitrofanoff procedure) to relieve bladder distention. If an incompetent urethral sphincter causes urinary leakage, injections, slings, or implants may be used to increase the urethral barrier. Recently, electrical stimulation of sacral roots has been used to initiate voiding. Biofeedback training is also used to improve voiding.

### 2. Neurogenic Bowel

Control of bowel function depends on an intact autonomic (sympathetic and parasympathetic) and somatic nervous system. Goals of treatment for patients with neurogenic bowel are to establish a predictable and reliable bowel habit, and prevent incontinence and complications. There are two types of neurogenic bowel dysfunction: upper motor and lower motor dysfunction. The upper neuron bowel results from damage above the conus. Affected patients usually have reflex bowel contractions of high amplitude, absence of sensation, and no voluntary sphincter control. Patients with the lower motor neuron bowel have no voluntary sphincter control and no reflex contraction of the external anal sphincter (anocutaneous reflex). It has been described as a flaccid bowel. In general, establishing a bowel program is easier in patients with upper motor neuron lesions.

#### Treatment

Fiber intake and fluids are critical elements for maintaining a soft stool consistency, although some patients try to keep themselves constipated to prevent accidents. A predictable and scheduled bowel program is essential. Bowel movements should be scheduled to occur with meals, as the gastrocolic reflex can trigger defecation.

Laxative and stool softening medications are usually included in a comprehensive bowel program. Stool softeners such as docusate retain stool water. Mineral oil is an acceptable stool softener in patients not at risk for pulmonary aspiration. Bulking agents such as Metamucil increase fiber and water content of stool and reduce transit time. Stimulants such as senna fruit extract or bisacodyl increase peristalsis. Osmotic agents such as polyethylene glycol keep stools soft by retaining stool water. Suppositories and enemas are often used when other methods have not been successful. Upper motor neuron bowel management programs may include digital rectal stimulation. When conservative methods are ineffective, options may include surgical implantation of sacral nerve stimulators or techniques to facilitate antegrade flushing of the colon. For example, the ACE (antegrade continence enema) or Malone procedure approximates the appendix to the surface of the abdomen providing a conduit for flushing. Also, a capped cecostomy tube can be placed into the cecum through which fluids can be administered in an antegrade fashion to remove fecal matter from the colon.

### 3. Spasticity

Spasticity is a velocity-dependent increase in muscle tone and a loss of isolated muscle function. Whereas tone is the resistance felt in a muscle as it is moved in space, spasticity occurs when there is damage to the CNS from trauma or injury. It is included in the upper motor neuron syndrome (hyperactive and exaggerated reflexes, increased tone, clonus, positive Babinski sign). Spasticity is evaluated using the Ashworth Scale, with 0 indicating no increase in muscle tone and 4 indicating complete rigidity of the extremity.
CHAPTER 28

» Treatment

Treatment is goal directed and influenced by the functional status of the client. Options for therapy range from conservative to aggressive. Children should be positioned properly and have appropriate equipment to prevent nociceptive input and facilitate physical therapy. Physical therapy can reduce the long-term effects of spasticity by use of stretching and range-of-motion exercises. Heat and cold are useful in improving tone, but their effects are not long lived. Casting of both upper and lower extremities can decrease tone and increase range of motion. Constraint therapy can be used to try to improve upper extremity function.

Pharmacologic support with medications, such as baclofen, diazepam, dantrolene, and tizanidine can be effective. Baclofen (a direct GABA\(_B\) agonist) is a first-line medication, which produces effects at the spinal cord level. Side effects are primarily sleepiness and weakness. Seizure threshold may be reduced by baclofen. Baclofen, delivered directly to the CNS through an intrathecal pump, has been used successfully in children with brain injury, cerebral palsy, and SCI. Diazepam, an allosteric modulator of postsynaptic GABA\(_A\) receptors in both the brain and the spinal cord, can be effective but its central CNS effects can cause drowsiness and dependence. Dantrolene inhibits excitation contraction coupling but use can result in weakness or, rarely, hepatotoxicity. Tizanidine is a newer agent and works at the \(\alpha_2\)-adrenergic receptors presynaptically. It can cause dry mouth and sedation, and liver function tests can be elevated.

Relief of focal spasticity can be achieved by using chemodenervation techniques. Botulinum toxin A and B can be injected in selected muscles to block acetylcholine release at the neuromuscular junction and thereby improve range of motion. Enhanced function, improved hygiene, reduced pain, and deformity are the result. Botulinum toxins have also been used to treat drooling, hyperhidrosis, and chronic pain. The effects are temporary, lasting only 3–6 months, and repeat injections are often needed. Technically more challenging phenol injection denatures proteins in both myelinated and unmyelinated fibers and produces neurolysis or myolysis, depending on the site of injection. The effects may last longer than botulinum toxins but carry a risk of sensory dysesthesia if mixed nerves are injected.

Surgical options include orthopedic procedures geared toward improving function and ambulation and alleviating deformities produced over time by spasticity. Contractures are common in the Achilles tendon, hamstrings, and adductors. Upper extremity contractures occur in the elbow, wrist, and finger flexors. Scoliosis is common and bracing or surgery may be needed. Gait analysis may be helpful in evaluating the child with functional spasticity as a guide for the use of orthotics, therapy, and surgery. Neurosurgical techniques such as selective dorsal rhizotomy, sectioning afferent sensory nerve fibers, are used in a very select group of children to permanently alter spasticity patterns and improve ambulation.

QUALITY ASSURANCE/IMPROVEMENT INITIATIVES IN REHABILITATION MEDICINE

Working with the Accreditation Council for Graduate Medical Education (ACGME), the American Academy of Physical Medicine and Rehabilitation (AAPM&R) fosters acquisition of knowledge regarding the use of quality assurance/ improvement techniques in its training programs. This is now one of six competencies required for board certification. The AAPM&R feels that these skills endow the practitioner with the capacity to maintain and improve the quality of care provided to the public.
Rheumatic Diseases

Jennifer B. Soep, MD

JUVENILE IDIOPATHIC ARTHRITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Arthritis, involving pain, swelling, warmth, tenderness, morning stiffness, and/or decreased range of motion of one or more joints, lasting at least 6 weeks.
- May have associated systemic manifestations, including fever, rash, uveitis, serositis, anemia, and fatigue.

Juvenile idiopathic arthritis (JIA) is characterized by chronic arthritis in one or more joints for at least 6 weeks. There are four main subtypes of JIA: (1) oligoarticular, (2) polyarticular, (3) systemic, and (4) enthesitis-associated. The exact cause of JIA is not known, but there is substantial evidence that it is an autoimmune process with genetic susceptibility factors.

Clinical Findings

A. Symptoms and Signs

The most common type of JIA is the oligoarticular form, which constitutes approximately 30%–40% of patients and is characterized by arthritis of four or fewer joints. This type often affects medium to large joints. Because the arthritis is often asymmetrical, children may develop a leg-length discrepancy in which the involved leg grows longer due to increased blood flow and growth factors. The synovitis is usually mild and may be painless. Systemic features are uncommon except for inflammation in the eye. Approximately 20% of children with oligoarticular arthritis develop insidious, asymptomatic uveitis, which may cause blindness if untreated. The activity of the eye disease does not correlate with that of the arthritis. Therefore, routine ophthalmologic screening with slit-lamp examination must be performed at 3-month intervals when the antinuclear antibody (ANA) test is positive, and at 6-month intervals if the ANA test is negative, for at least 4 years after the onset of arthritis, as this is the period of highest risk.

Polyarticular disease, which is defined as arthritis involving five or more joints accounts for 25% of JIA. Both large and small joints are involved, typically in a symmetrical pattern. Systemic features are not prominent, although low-grade fever, fatigue, rheumatoid nodules, and anemia may be present. This group is further divided into rheumatoid factor (RF)-positive and RF-negative disease. The former resembles adult rheumatoid arthritis with more chronic, destructive arthritis.

The systemic form, previously known as Still disease, comprises 5%–10% of patients with JIA. The arthritis can involve any number of joints and affects both large and small joints, but may be absent at disease onset. One of the classic features is a high fever, often as high as 39°C–40°C, typically occurring one to two times per day. In between fever spikes, the temperature usually returns to normal or subnormal. Around 90% patients have a characteristic evanescent, salmon-pink macular rash that is most prominent on pressure areas and when fever is present. Other systemic features that may be present, but are not specific for JIA, include hepatosplenomegaly, lymphadenopathy, leukocytosis, and serositis.

Enthesitis-associated arthritis is most common in males, older than 10 years of age, and is typically associated with lower extremity, large joint arthritis. The hallmark of this form is inflammation of tendinous insertions (enthesitis), such as the tibial tubercle or the heel. Low back pain and sacroiliitis are also commonly seen. This form of arthritis comprises approximately 10%–20% of patients with JIA.
There are two additional subtypes of JIA. Children with psoriatic arthritis may have typical psoriasis, but may also present prior to the onset of the classic scaly plaques and have more subtle changes such as nail pitting. Patients with psoriatic arthritis may also present with dactylitis or “sausage digit,” which is painful swelling of an entire finger or toe. Undifferentiated JIA, comprising 10% of patients, includes children with chronic arthritis that do not meet criteria for any of the other subgroups or meet more than one criterion and therefore could be classified into multiple subgroups.

B. Laboratory Findings

There is no diagnostic test for JIA. A normal erythrocyte sedimentation rate (ESR) does not exclude the diagnosis of JIA. However, patients with systemic JIA typically have significantly elevated markers of inflammation, including ESR, C-reactive protein (CRP), white blood cell count, and platelets. RF is positive in about 5% of patients, usually when the onset of polyarticular disease occurs after age 8 years. The anti-cyclic citrullinated peptide (anti-CCP) antibody, has a very high specificity for rheumatoid arthritis and may be detectable prior to the RF. ANAs are associated with an increased risk of uveitis in patients with oligoarticular disease. A positive ANA test is also fairly common in patients with the late-onset RF-positive form of the disease. Carriage of HLAB27 antigen is associated with an increased risk of developing enthesitis-associated arthritis.

Table 29–1 lists the general characteristics of joint fluid in various conditions. The main indication for joint aspiration and synovial fluid analysis is to rule out infection. A positive Gram stain or culture is the only definitive test for infection. A leukocyte count over 2000/μL suggests inflammation; and no daytime symptoms. Patients with a positive ANA test is also fairly common in patients with the late-onset RF-positive form of the disease. Table 29–1 lists the general characteristics of joint fluid in various conditions. The main indication for joint aspiration and synovial fluid analysis is to rule out infection. A positive Gram stain or culture is the only definitive test for infection. A leukocyte count over 2000/μL suggests inflammation; and no daytime symptoms. C. Imaging Studies

In the early stages of the disease, only soft tissue swelling and possibly periarticular osteoporosis may be seen. Magnetic resonance imaging (MRI) of involved joints may show early joint damage and, if obtained with gadolinium, can confirm the presence of synovitis. Ultrasound is now used to detect synovitis, tenosynovitis, and bony erosions without radiation and without requiring sedation. Later in the course of the disease, particularly in patients with RF-positive disease, plain films may demonstrate joint space narrowing due to cartilage thinning and erosive changes of the bone related to chronic inflammation.

Differential Diagnosis

Table 29–2 lists the most common causes of limb pain in childhood. JIA is a diagnosis of exclusion; therefore, it is important to rule out other causes of the clinical signs and symptoms prior to settling on this diagnosis. The differential diagnosis is often quite broad, including orthopedic conditions, infectious diseases, and malignancies. A few key features can help distinguish these different entities, including the timing of the pain and associated signs and symptoms. In inflammatory conditions, patients frequently have increased symptoms in the morning with associated stiffness, whereas, patients with an orthopedic abnormality typically have increased symptoms later in the day and with activity. Growing pains, a common cause of leg pain in childhood, are characterized by poorly localized pain at night, which frequently wakes the child from sleep; no objective signs of inflammation; and no daytime symptoms. Patients with growing pains often ask to be massaged, which is not typical of those with arthritis.

It is particularly important to establish the diagnosis in the case of monoarticular arthritis. Bacterial arthritis is usually acute and monoarticular except for arthritis associated with gonorrhea, which may be associated with a migratory pattern and hemorrhagic pustules, usually on the distal extremities. Fever, leukocytosis, and increased ESR with an acute process in a single joint demand synovial fluid examination and culture to identify the pathogen. Pain in the hip or lower extremity is a frequent symptom of childhood cancer, especially leukemia, neuroblastoma, and rhabdomyosarcoma. Infiltration of bone by tumor and a joint effusion may be seen. Radiographs of the affected site and examination of the blood smear for unusual cells and thrombocytopenia are necessary. An elevated lactate dehydrogenase value should also raise concern about an underlying neoplastic process. In doubtful cases, bone marrow examination is indicated.

Reactive arthritis is joint pain and swelling triggered by an infection. The infection is nonarticular and can be...
either viral or bacterial. A preceding illness is identified in approximately half of cases. Patients often have acute onset of arthritis, and there may be a migratory pattern. The duration of symptoms is a very important distinction between reactive arthritides and JIA. Symptoms associated with reactive arthritis typically resolve within 4–6 weeks. In contrast, to meet criteria for chronic arthritis, symptoms must be present for at least 6 weeks.

The arthritis of rheumatic fever is migratory, transient, and often more painful than that of JIA. Rheumatic fever is very rare in children younger than 5 years (see Chapter 20).

In suspected cases, evidence of rheumatic carditis should be sought based on examination and electrocardiographic findings. Evidence of recent streptococcal infection is essential to the diagnosis. The fever pattern in rheumatic fever is low grade and persistent compared with the spiking fever that characterizes the systemic form of JIA. Lyme arthritis resembles oligoarticular JIA, but the former usually occurs as discrete, recurrent episodes of arthritis lasting 2–6 weeks and children should have a history of being in an endemic area. The typical bull’s-eye rash, erythema chronicum migrans, is reported for approximately 70%–80% of patients, although it is resolved by the time the arthritis appears. For children suspected of having Lyme disease, testing for antibodies against *Borrelia burgdorferi* should be performed, with confirmatory testing by Western blot.

### Treatment

The objectives of therapy are to restore function, relieve pain, maintain joint motion, and prevent damage to cartilage and bone.

#### A. Nonsteroidal Anti-Inflammatory Medications

Nonsteroidal anti-inflammatory drugs (NSAIDs) are frequently used for symptomatic relief. A wide range of agents is available but only a few are approved for use in children, including naproxen (10 mg/kg per dose twice daily), ibuprofen (10 mg/kg per dose three to four times daily), and meloxicam (0.125–0.25 mg/kg once daily). NSAIDs are generally well tolerated in children, as long as they are taken with food. The average time to symptomatic improvement is 1 month, but in some patients a response is not seen for 8–12 weeks.

#### B. Disease-Modifying and Biologic Agents

Most patients with JIA require treatment with a disease-modifying medication, most commonly weekly methotrexate. Symptomatic response usually begins within 3–4 weeks. The low dosages used (5–10 mg/m²/wk or up to 1 mg/kg/wk as a single dose) are generally well tolerated. Potential side effects include nausea, vomiting, hair thinning, stomatitis, leukopenia, immunosuppression, and hepatotoxicity. A complete blood count and liver function tests should be obtained every 2–3 months. Several additional disease-modifying agents are available for use in patients with persistently active disease or those intolerant to methotrexate. Leflunomide is an antipyrimidine medication that is administered orally. Side effects may include diarrhea and alopecia. Biological modifying medications that inhibit tumor necrosis factor, a cytokine known to play an important role in the pathogenesis of JIA, include etanercept, infliximab, and adalimumab. These drugs are generally quite effective in controlling disease and preventing

cartilage and bone damage, and have been associated with healing based on radiologic changes. However, their potential long-term effects are less well understood, they are very expensive, and require parenteral administration. Anakinra and tocilizumab, which block interleukin 1 and 6, respectively, are particularly effective for systemic JIA. Other biologic agents, including rituximab and abatacept, have demonstrated some efficacy in patients who have not responded to other treatments.

C. Corticosteroids

Local steroid joint injections may be helpful in patients who have arthritis in one or a few joints. Triamcinolone acetonide is a long-acting steroid that can be used for injections and is often associated with at least several months of disease control. Oral or parenteral steroids are reserved for children with severe involvement, primarily patients with systemic disease.

D. Uveitis

Inflammation of the uveal tract (uveitis or iridocyclitis) should be closely monitored by an ophthalmologist. Typically treatment is initiated with corticosteroid eye drops and dilating agents to prevent scarring between the iris and the lens. In patients who fail topical treatments, methotrexate, cyclosporine, mycophenolate mofetil, and/or a tumor necrosis factor inhibitor such as infliximab or adalimumab may be used.

E. Rehabilitation

Physical and occupational therapies are important to focus on range of motion, stretching, and strengthening. These exercises, as well as other modalities such as heat, water therapy, and ultrasound, can help control pain, maintain and restore function, and prevent deformity and disability. Young children with oligoarticular disease affecting asymmetrical lower extremity joints can develop a leg-length discrepancy, which may require treatment with a shoe lift on the shorter side.

Prognosis

The course and prognosis for JIA is variable, depending on the subtype of disease. Children with persistent oligoarticular JIA have the highest rate of clinical remission, while patients with RF-positive disease are the least likely to achieve this status and are at highest risk for chronic, erosive arthritis that may continue into adulthood. The systemic features associated with systemic arthritis tend to remit within months to years. The prognosis in systemic disease is worse in patients with persistent systemic disease after 6 months, thrombocytosis, and more extensive arthritis.

SYSTEMIC LUPUS ERYTHEMATOSUS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

Multisystem inflammatory disease of the joints, serosal linings, skin, kidneys, blood, and central nervous system.

Pathogenesis

Systemic lupus erythematosus (SLE) is the prototype of immune complex diseases; its pathogenesis is related to the formation of antibody–antigen complexes that exist in the circulation and deposit in the involved tissues. The spectrum of symptoms is due to tissue-specific autoantibodies as well as the damage to tissues by lymphocytes, neutrophils, and complement evoked by the deposition of immune complexes.

Clinical Findings

A. Symptoms and Signs

The onset of pediatric SLE is most common in girls between the ages of 9 and 15 years. Signs and symptoms depend on the organs affected by immune complex deposition. The American College of Rheumatology has established classification criteria for SLE; four of the following 11 criteria are necessary to be classified as SLE:

1. Malar rash—photosensitive, “butterfly rash” on the cheeks and nasal bridge
2. Discoid rash—annular, scaly rash on the scalp, face, and extremities that can lead to scarring
3. Photosensitivity—increased rash or other disease symptoms in response to sunlight exposure
4. Mucous membrane ulcers—painless ulcers on the hard palate and/or nasal septum
5. Arthritis—nonerosive arthritis of large and small joints, typically in a symmetrical distribution

6. Serositis—pericarditis and/or pleuritis, often associated with chest pain and difficulty breathing
7. Renal abnormalities—proteinuria (> 0.5 g/d) and/or cellular casts
8. Neurologic abnormalities—seizures and/or psychosis
9. Blood count abnormalities—low white blood cell count (< 4000/mm³), Coombs test–positive anemia, and/or thrombocytopenia (< 100,000/mm³)
10. Positive ANA—seen in almost 100% of patients with SLE
11. Autoantibodies—positive double-stranded DNA antibody, anti-Smith antibody, anticardiolipin antibodies, lupus anticoagulant, and/or false-positive blood test for syphilis

Other common signs and symptoms include fever, fatigue, weight loss, anorexia, Raynaud phenomenon, myositis, and vasculitis.

B. Laboratory Findings

Blood count abnormalities are common, including leukopenia, anemia, and thrombocytopenia. Approximately 15% of patients are Coombs test–positive, but many patients develop anemia due to other causes, including chronic disease and blood loss. Patients with significant renal involvement may have electrolyte disturbances, elevated kidney function tests, and hypoalbuminemia. The ESR is frequently elevated during active disease. In contrast, many patients with active SLE have a normal CRP. When the CRP is elevated, it is important to investigate possible infectious causes, particularly bacterial infections. It is critical to monitor the urinalysis in patients with SLE for proteinuria and hematuria, as the renal disease may be otherwise clinically silent. In immune complex diseases, complement is consumed; therefore, levels of C3 and C4 are depressed with active disease.

The ANA test is positive in almost 100% of patients, usually at titers of 1:320 or above. In patients with suspected SLE, it is important to obtain a full ANA profile—including antibodies directed against double-stranded DNA, Smith, ribonucleic protein, and Sjögren-specific antibody A and B to better characterize their serologic markers of disease. Because approximately 50%–60% of pediatric SLE patients have antiphospholipid antibodies and are therefore at increased risk of thrombosis, it is important to screen all patients with SLE for anticardiolipin antibodies and lupus anticoagulant.

Differential Diagnosis

Because there is such a wide spectrum of disease with SLE, the differential diagnosis is quite broad, including systemic JIA, mixed connective tissue disease (MCTD), rheumatic fever, vasculitis, malignancies, and bacterial and viral infections. A negative ANA test essentially excludes the diagnosis of SLE. Anti–double-stranded DNA and Smith antibodies are very specific for SLE. The preceding classification criteria, which can be very helpful in establishing the diagnosis of SLE, have a specificity and sensitivity of 96%.

MCTD, an overlap syndrome with features of several rheumatologic diseases, shares many signs and symptoms with SLE. The symptom complex is diverse and often includes arthritis, fever, skin tightening, Raynaud phenomenon, muscle weakness, and rash. The ANA test is typically positive in very high titer. The ANA profile is negative except for antibodies directed against ribonucleic protein.

Treatment

The treatment of SLE should be tailored to the organ system involved so that toxicities may be minimized. Prednisone is the mainstay of treatment and has significantly lowered the mortality rate in SLE. Patients with severe, life-threatening, or organ-threatening disease are typically treated with intravenous pulse methylprednisolone, 30 mg/kg per dose (maximum of 1000 mg) daily for 3 days, and then switched to 2 mg/kg/d of prednisone. The dosage should be adjusted using clinical and laboratory parameters of disease activity, and the minimum amount of corticosteroid to control the disease should be used. Skin manifestations, arthritis, and fatigue may be treated with antimalarials such as hydroxychloroquine, 5–7 mg/kg/d orally. Pleuritic pain or arthritis can often be managed with NSAIDs.

If disease control is inadequate with prednisone or if the dose required produces intolerable side effects, a steroid-sparing agent, such as mycophenolate mofetil, azathioprine, or cyclophosphamide, should be added. More recently, rituximab, a monoclonal antibody directed against the B-cell surface marker CD20, has been used for persistent active disease. Patients who have evidence of antiphospholipid antibodies should be treated with a baby aspirin every day to help prevent thrombosis. Thrombotic events due to these antibodies require long-term anticoagulation.

The toxicities of the regimens must be carefully considered. Growth failure, osteoporosis, Cushing syndrome, adrenal suppression, and aseptic bone necrosis are serious side effects of chronic use of prednisone. When high doses of corticosteroids are used (> 2 mg/kg/d), there is a high risk of infection. Cyclophosphamide can cause bone marrow suppression, bladder epithelial dysplasia, hemorrhagic cystitis, and sterility. Azathioprine has been associated with liver damage and bone marrow suppression. Immunosuppressant treatment should be withheld if the total white blood cell count falls below 3000/mm³ or the neutrophil count falls below 1000/mm³. Retinal damage from hydroxychloroquine is generally not observed with recommended dosages, but patients should have routine visual field testing to screen for retinal toxicity.
CHAPTER 29

**Prognosis**

The disease has a natural waxing and waning cycle; it may flare at any time and spontaneous remission may rarely occur. The 5-year survival rate has improved from 51% in 1954 to 90% today. Factors that have contributed to improved prognosis include earlier diagnosis, more aggressive treatments with cytotoxic/immunosuppressive agents, pulse high-dose steroids, and advances in the treatment of hypertension, infections, and renal failure.

**DERMATOMYOSITIS**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Pathognomonic skin rashes.
- Weakness of proximal muscles and occasionally of pharyngeal and laryngeal groups.
- Pathogenesis related to vasculopathy.

**Clinical Findings**

**A. Symptoms and Signs**

The predominant symptom is proximal muscle weakness, particularly affecting pelvic and shoulder girdle muscles. Tenderness, stiffness, and swelling may be found. Pharyngeal involvement, manifested as voice changes and difficulty swallowing, is associated with an increased risk of aspiration. Intestinal vasculitis can be associated with ulceration and perforation of involved areas. Flexion contractures and muscle atrophy may produce significant residual deformities. Calcinosis may follow the inflammation in muscle and skin.

Several characteristic rashes are seen in dermatomyositis. Patients often have a heliotrope rash with a reddish-purple hue on the upper eyelids, along with a malar rash that may be accompanied by edema of the eyelids and face. Gottron papules are shiny, erythematous, scaly plaques on the extensor surfaces of the knuckles, elbows, and knees. Dilated nail-bed vessels are commonly seen with active disease. Thrombosis and dropout of periungual capillaries may identify patients with a more severe, chronic disease course.

**B. Laboratory Findings/Imaging Studies/Special Tests**

Determination of muscle enzyme levels, including aspartate aminotransferase, alanine aminotransferase, lactate dehydrogenase, creatine phosphokinase, and aldolase, is helpful in confirming the diagnosis, assessing disease activity, and monitoring the response to treatment. Even in the face of extensive muscle inflammation, the ESR and CRP may be normal. An MRI scan of the quadriceps muscles can be used in equivocal cases to confirm the presence of inflammatory myositis. Electromyography is useful to distinguish myopathic from neurogenic causes of muscle weakness. Muscle biopsy is indicated in cases of myositis without the pathognomonic rash.

**Treatment**

Treatment is aimed at suppression of the inflammatory response and prevention of the loss of muscle function and joint range of motion. Acutely, it is very important to assess the adequacy of the ventilatory effort and swallowing, and to rule out intestinal vasculitis. Corticosteroids are the initial therapy of choice. Treatment is usually initiated with prednisone, 2 mg/kg/d, and continued until signs and symptoms of active disease are controlled; the dosage is then gradually tapered. In severe cases, intravenous pulse methylprednisolone for 3 days is indicated. Therapy is guided by the physical examination findings and muscle enzyme values. Methotrexate is often used concomitantly to achieve better control of the disease and minimize the steroid side effects. If patients continue to have active disease, additional steroid-sparing agents, such as mycophenolate mofetil, cyclosporine, intravenous immunoglobulin, and, in severe cases, rituximab or cyclophosphamide may be considered.

Hydroxychloroquine and intravenous immunoglobulin may be particularly helpful in managing the skin manifestations. As the rashes are photosensitive, sun protection is very important. Physical and occupational therapy should be initiated early in the course of disease. Initially, passive range-of-motion exercises are performed to prevent loss of motion. Later, once the muscle enzymes have normalized, a graduated program of stretching and strengthening exercises is introduced to restore normal strength and function.

**Prognosis**

Most patients have a monocyclic course; 10%–20% of patients have more chronic or recurrent symptoms.
Factors that influence the outcome include the rapidity of symptom onset, extent of weakness, presence of cutaneous or gastrointestinal vasculitis, timeliness of diagnosis, initiation of therapy, and response to treatment. Dermatomyositis in children is not associated with cancer as it is in adults.

<td>Microscopic polyarteritis</td>
</tr>
</tbody>
</table>

Granulomatosis with polyangiitis (previously called Wegener granulomatosis) often causes nephritis and involves the lungs, manifesting as chronic cough, hemorrhage, and/or cavitating lesions. This form of vasculitis also frequently affects the upper respiratory tract, causing chronic otitis media, sinusitis, and/or inflammation of the trachea; saddle nose deformity may occur.

Children with polyarteritis nodosa (PAN) often present with skin lesions such as purpura, nodules or ulcers, and evidence of organ involvement with abdominal pain, testicular pain, hypertension, hematuria, and/or neurologic symptoms. MPA typically presents with pulmonary-renal syndrome with features of pulmonary hemorrhage and rapidly progressive kidney inflammation.

### B. Laboratory Findings/Imaging Studies/Special Tests

Patients with vasculitis often have elevated inflammatory markers. If they have significant renal involvement, they may have elevated renal function tests and abnormal urinary sediment. Anemia is common, due to chronic disease and/or renal insufficiency. Low hemoglobin may also be an indicator of pulmonary hemorrhage in a patient with cough, hemoptysis, respiratory distress, and/or infiltrates on chest x-ray.

Antineutrophil cytoplasmic antibodies (ANCA) may be present in patients with small vessel vasculitis. Cytoplasmic ANCA (c-ANCA), which is usually directed against proteinase 3 and is quite sensitive and specific for GPA, is positive in 80%–95% of patients. Perinuclear ANCA (p-ANCA) is typically directed against myeloperoxidase and is associated with MPA and can also be seen in HSP, Churg-Strauss, and inflammatory bowel disease.

The diagnosis is made based on a typical clinical presentation and laboratory findings. If the diagnosis remains uncertain, then attempting to establish the diagnosis with a...
biopsy of involved tissue is warranted. A biopsy in patients with GPA typically demonstrates necrotizing granulomatous vasculitis. Biopsies of involved areas will confirm the presence of vasculitis in small vessels in patients with MPA and small and medium arteries in PAN. If a biopsy is not feasible, additional imaging studies such as an angiogram, which can demonstrate characteristic patterns of inflammation in affected blood vessels, should be considered.

**Treatment**

The treatment of the various forms of chronic vasculitis is based on the severity of illness and the organs involved. Typically, corticosteroids are the initial therapy. Patients with severe disease are usually treated with intravenous pulse methylprednisolone, 30 mg/kg per dose (maximum of 1000 mg) daily for 3 days, and then switched to 2 mg/kg/d of prednisone. The dosage is then gradually tapered as tolerated based on clinical and laboratory markers of disease activity. Patients are usually treated with other immunosuppressant medications to gain and maintain control of the disease and minimize the steroid side effects. Standard treatment has included cyclophosphamide for induction, followed by maintenance with methotrexate, azathioprine, or mycophenolate. More recent studies in patients with ANCA-positive vasculitis suggest that rituximab can be used for induction therapy with potentially fewer side effects and risks than cyclophosphamide.

**Prognosis**

Immunosuppressive medications have improved survival and remission rates for patients with chronic vasculitis. Conditions such as GPA had almost always been fatal. Since introducing the regimen of high-dose steroids and cyclophosphamide (or other cytotoxic agents), patients with vasculitides have greatly improved outcomes, with 5-year survival ranging from 50% to 100%. Because relapses are common when therapy is weaned or stopped, maintenance immunosuppression is commonly required.

**NONINFLAMMATORY PAIN SYNDROMES**

1. **Complex Regional Pain Syndrome**

Complex regional pain syndrome, previously known as reflex sympathetic dystrophy, is a painful condition that is frequently confused with arthritis. Prevalence and recognition of the condition is increasing. Severe extremity pain leading to nearly complete loss of function is the hallmark of the condition. Evidence of autonomic dysfunction is demonstrated by pallor or cyanosis, temperature differences (with the affected extremity cooler than surrounding areas), and generalized swelling. On examination, allodynia, which is marked cutaneous hyperesthesia to even the slightest touch, is often evident. Results of laboratory tests are normal, without evidence of systemic inflammation. Radiographic findings are normal except for late development of osteoporosis. Bone scans may be helpful and may demonstrate either increased or decreased blood flow to the painful extremity.

The cause of this condition remains elusive. Treatment includes physical therapy to focus on restoration of function, maintenance of range of motion, and pain relief. NSAIDs can be helpful for pain control; in patients with more chronic disease, gabapentin, or pregabalin are frequently effective. Persistent disease may respond to local nerve blocks. Counseling is helpful to identify potential psychosocial stressors and to assist with pain management. Long-term prognosis is good if recovery is rapid; recurrent episodes imply a less favorable prognosis.
2. Fibromyalgia

Fibromyalgia is a chronic pain syndrome characterized by diffuse musculoskeletal pain, fatigue, sleep disturbance, and chronic headaches. Weather changes, fatigue, and stress exacerbate symptoms. Patients have a normal examination except for characteristic trigger points at the insertion of muscles, especially along the neck, spine, and pelvis.

Treatment centers on physical therapy, nonnarcotic pain medications, improving sleep, and counseling. Low-dose amitriptyline or trazodone can help with sleep and may produce remarkable reduction in pain. Physical therapy should emphasize a graded rehabilitative approach to stretching and exercise and promote regular aerobic exercise. Pregabalin recently became the first medication to be approved by the Food and Drug Administration for the treatment of fibromyalgia. Use of the drug is associated with decreased pain in adults with fibromyalgia, and studies are planned to test safety and efficacy in children with the condition. The prognosis for children with fibromyalgia is not clear, and long-term strategies may be necessary to enable them to cope with the condition.

3. Hypermobility Syndrome

Ligamentous laxity is a common cause of joint pain. Patients with hypermobility present with episodic joint pain and occasionally with swelling that lasts a few days after increased physical activity. Depending on the activity, almost any joint may be affected. Five criteria have been established: (1) passive opposition of the thumb to the flexor surface of the forearm, (2) passive hyperextension of the fingers so that they are parallel to the extensor surface of the forearm, (3) hyperextension of the elbow, (4) hyperextension of the knee, and (5) palms on floor with knees extended. Results of laboratory tests are normal. The pain associated with the syndrome is produced by improper joint alignment caused by the laxity during exercise. Treatment consists of a graded conditioning program designed to provide muscular support of the joints to compensate for the loose ligaments and to train patients to protect their joints from hyperextension.

Constitutional and acquired aplastic anemias are discussed in this section and the more common single cytopenias in later sections. Bone marrow failure caused by malignancy or other infiltrative disease is discussed in this chapter. It is important to remember that many drugs and toxins may affect the marrow and cause single or multiple cytopenias.

Suspicion of bone marrow failure is warranted in children with pancytopenia and in children with single cytopenias who lack evidence of peripheral red cell, white cell, or platelet destruction. Macrocytosis often accompanies bone marrow failure. Many of the constitutional bone marrow disorders are associated with a variety of congenital anomalies.

**NORMAL HEMATOLOGIC VALUES**

The normal ranges for peripheral blood counts vary significantly with age. Normal neonates have a hematocrit of 45%–65%. The reticulocyte count at birth is relatively high at 2%–8%. Within the first few days of life, erythrocyte production decreases, and the values for hemoglobin and hematocrit fall to a nadir at about 6–8 weeks. During this period, known as physiologic anemia of infancy, normal infants have hemoglobin values as low as 10 g/dL and hematocrits as low as 30%. Thereafter, the normal values for hemoglobin and hematocrit gradually increase until adult values are reached after puberty. Premature infants can reach a nadir hemoglobin level of 7–8 g/dL at 8–10 weeks. Anemia is defined as a hemoglobin concentration two standard deviations below the mean for a normal population of the same gender and age.

Newborns have larger red cells than children and adults, with a mean corpuscular volume (MCV) at birth of more than 94 fl. The MCV subsequently falls to a nadir of 70–84 fl at about age 6 months. Thereafter, the normal MCV increases gradually until it reaches adult values after puberty.

The normal number of white blood cells (WBCs) is higher in infancy and early childhood than later in life. Neutrophils predominate in the differential white count at birth and in the older child. Lymphocytes predominate (up to 80%) between about ages 1 month and 6 years.

Normal values for the platelet count are 150,000–400,000/μL and vary little with age.

**CONSTITUTIONAL APLASTIC ANEMIA (FANCONI ANEMIA)**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Progressive pancytopenia.
- Macrocytosis.
- Multiple congenital anomalies in two-thirds
- Increased chromosome breakage in peripheral blood lymphocytes.

**General Considerations**

Fanconi anemia, which is the most common inherited bone marrow failure syndrome, is caused by germline mutations in the repair genes of the FA/BRCA pathway.
is generally autosomal recessive, and the disease occurs in all ethnic groups; 75%–90% of affected individuals develop bone marrow failure in the first 10 years of life.

► Clinical Findings
A. Symptoms and Signs
Symptoms are determined principally by the degree of hematologic abnormality. Thrombocytopenia may cause purpura, petechiae, and bleeding; neutropenia may cause severe or recurrent infections; and anemia may cause weakness, fatigue, and pallor. Congenital anomalies are present in at least two-thirds of patients. The most common anomalies include abnormal pigmentation of the skin (generalized hyperpigmentation, café au lait or hypopigmented spots), short stature with delicate features, and skeletal malformations (hypoplasia, anomalies, or absence of the thumb and radius). More subtle anomalies are hypoplasia of the thenar eminence or a weak or absent radial pulse. Associated renal anomalies include aplasia, horseshoe kidney, and duplication of the collecting system. Other anomalies are microcephaly, microphthalmia, strabismus, ear anomalies, and hypogenitalism.

B. Laboratory Findings
Thrombocytopenia or leukopenia typically occurs first, followed over the course of months to years by anemia and progression to severe aplastic anemia. Macrocytosis, which is virtually always present, is usually associated with anisocytosis and an elevation in fetal hemoglobin levels, and is an important diagnostic clue. The bone marrow reveals hypoplasia or aplasia. The diagnosis is confirmed by demonstration of an increased number of chromosome breaks and rearrangements in peripheral blood lymphocytes. The use of diepoxybutane to stimulate the breaks and rearrangements provides a sensitive assay that is virtually always positive in children with Fanconi anemia, even before the onset of hematologic abnormalities.

Specific Fanconi genes (FANC A, B, C, and others) have been identified and transmission is generally autosomal recessive, although FANCB is X-linked.

► Differential Diagnosis
Because patients with Fanconi anemia frequently present with thrombocytopenia, the disorder must be differentiated from idiopathic thrombocyticopenic purpura (ITP) and other more common causes of thrombocytopenia. In contrast to patients with ITP, those with Fanconi anemia usually exhibit a gradual fall in the platelet count. Counts less than 20,000/μL are often accompanied by neutropenia or anemia. Fanconi anemia may also be manifested initially by pancytopenia, and must be differentiated from acquired aplastic anemia and other disorders, such as acute leukemia. Examination of the bone marrow and chromosome studies of peripheral blood lymphocytes (chromosomal breakage) will usually distinguish between these disorders.

► Complications
Complications are those related to thrombocytopenia and neutropenia. Endocrine dysfunction may include growth hormone deficiency, hypothyroidism, or impaired glucose metabolism. Persons with Fanconi anemia have a significantly increased risk of developing malignancies, especially acute nonlymphocytic leukemia (800-fold), head and neck cancers, genital cancers, and myelodysplastic syndromes related to defective DNA repair.

► Treatment
Attentive supportive care is critical. Patients with neutropenia who develop fever require prompt evaluation and parenteral broad-spectrum antibiotics. Transfusions are important, but should be used judiciously, especially in the management of thrombocytopenia, which frequently becomes refractory to platelet transfusions as a consequence of alloimmunization. Transfusions from family members should be discouraged because of the negative effect on the outcome of bone marrow transplant. At least 50% of patients with Fanconi anemia respond, albeit incompletely, to oxymetholone, and many recommend institution of androgen therapy before transfusions are needed. However, oxymetholone is associated with hepatotoxicity, hepatic adenomas, and masculinization, and is particularly troublesome for female patients.

The definitive treatment is a reduced intensity hematopoietic stem cell transplant, ideally from a human leukocyte antigen (HLA)–identical sibling donor, although matched unrelated and cord transplant may be considered. Before transplant, a prospective sibling donor must be screened for Fanconi anemia.

► Prognosis
Many patients succumb to bleeding, infection, or malignancy in adolescence or early adulthood. Hematopoietic stem cell transplant does not reduce the increased susceptibility for malignancy; 40% develop malignancy by twenty years post-transplant.

ACQUIRED APLASTIC ANEMIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Weakness and pallor.
- Petechiae, purpura, and bleeding.
- Frequent or severe infections.
- Pancytopenia with hypocellular bone marrow.

General Considerations

Acquired aplastic anemia is characterized by peripheral pancytopenia with a hypocellular bone marrow. Approximately 70% of cases in childhood are idiopathic. Other cases are secondary to idiosyncratic reactions to drugs such as phenylbutazone, sulfonamides, nonsteroidal anti-inflammatory drugs (NSAIDs), and anticonvulsants. Toxic causes include exposure to benzene, insecticides, and heavy metals. Infectious causes include viral hepatitis, infectious mononucleosis (Epstein-Barr virus [EBV]), and human immunodeficiency virus (HIV). In immunocompromised children, aplastic anemia has been associated with human parvovirus B19 infection. Immune dysregulation can be associated with anemia.

Clinical Findings

A. Symptoms and Signs

Weakness, fatigue, and pallor result from anemia; petechiae, purpura, and bleeding occur due to thrombocytopenia; and fevers due to generalized or localized infections are associated with neutropenia. Hepatosplenomegaly and significant lymphadenopathy are unusual.

B. Laboratory Findings

Anemia is usually normocytic, with a low reticulocyte count. The WBC count is low, with a marked neutropenia. The platelet count is typically below 50,000/μL and is frequently below 20,000/μL. Bone marrow biopsy shows a marked decrease in cellularity, typically less than 20% and less than 50% of normal, in severe and moderate aplastic anemia, respectively.

Differential Diagnosis

Examination of the bone marrow usually excludes pancytopenia caused by peripheral destruction of blood cells or by infiltrative processes such as acute leukemia, storage diseases, and myelofibrosis. Many of these other conditions are associated with hepatosplenomegaly. Preleukemic conditions also may present with pancytopenia and hypocellular bone marrows. Cytogenetic analysis of the marrow is helpful, because a clonal abnormality may predict the subsequent development of leukemia. Since congenital anomalies may not be apparent in some children with Fanconi anemia, patients with newly diagnosed aplastic anemia should be studied for chromosome breaks and rearrangements in peripheral blood lymphocytes.

Complications

Acquired aplastic anemia is characteristically complicated by infection and hemorrhage, which are the leading causes of death. Other complications are those associated with therapy.

Treatment

Comprehensive supportive care is essential. Febrile illnesses require prompt evaluation and usually parenteral antibiotics. Red blood cell (RBC) transfusions alleviate symptoms of anemia. Platelet transfusions may be lifesaving, but they should be used sparingly because many patients eventually develop platelet alloantibodies and become refractory to platelet transfusions.

Immunomodulation, usually with antithymocyte globulin and cyclosporine or tacrolimus, is associated with a high response rate and improved overall survival. The addition of eltrombopag, a thrombopoietin mimic, may be advantageous. However, incomplete response, relapse, and progression to myelodysplasia/leukemia may occur. Hematopoietic stem cell transplant is the treatment of choice for severe aplastic anemia when an HLA-identical sibling donor is available. Because the likelihood of success with transplant is influenced adversely by receipt of transfusions, HLA typing of family members should be undertaken at the time of diagnosis. Increasingly, patients who lack HLA-identical siblings are able to find matched donors through cord blood banks or the National Marrow Donor Program.

Prognosis

Children receiving early bone marrow transplant from an HLA-identical sibling have a long-term survival rate of greater than 90%. Sustained, complete remissions may be seen in 65%–80% of patients receiving immunosuppressive therapy. However, all survivors are at an increased risk of myelodysplastic syndrome, acute leukemia, and other malignancies.

Anemia is a relatively common finding, and identifying the cause is important. Even though anemia in childhood has many causes, the correct diagnosis can usually be established with relatively little laboratory cost. Frequently the cause is identified with a careful history. Nutritional causes should be sought by inquiry about dietary intake; growth and development; and symptoms of chronic disease, malabsorption, or blood loss. Hemolytic disease may be associated with a history of jaundice (including neonatal jaundice) or by a family history of anemia, jaundice, gallbladder disease, splenomegaly, or splenectomy. The child’s ethnicity may suggest the possibility of certain hemoglobinopathies or deficiencies of red cell enzymes, such as glucose-6-phosphate dehydrogenase (G6PD). The review of systems may reveal clues to a previously unsuspected systemic disease associated with anemia. The patient’s age is important because some causes of anemia are age related. For example, patients with iron deficiency anemia (IDA) and β-globin disorders present more commonly at ages 6–36 months than at other times in life.

The physical examination may also reveal clues to the cause of anemia. Poor growth may suggest chronic disease or hypothyroidism. Congenital anomalies may be associated with constitutional aplastic anemia (Fanconi anemia) or with congenital hypoplastic anemia (Diamond-Blackfan anemia). Other disorders may be suggested by the findings of petechiae or purpura (leukemia, aplastic anemia, hemolytic uremic syndrome), jaundice (hemolysis or liver disease), generalized lymphadenopathy (leukemia, juvenile rheumatoid arthritis, HIV infection), splenomegaly (leukemia, sickle hemoglobinopathy syndromes, hereditary spherocytosis, liver disease, hypersplenism), or evidence of chronic or recurrent infections.

The initial laboratory evaluation of the anemic child consists of a complete blood count (CBC) with differential and platelet count, review of the peripheral blood smear, and a reticulocyte count. The algorithm in Figure 30–1 uses limited laboratory information, together with the history

![Figure 30–1. Investigation of anemia.](image-url)
and physical examination, to reach a specific diagnosis or to focus additional laboratory investigations on a limited diagnostic category (eg, microcytic anemia, bone marrow failure, pure red cell aplasia, or hemolytic disease). This diagnostic scheme depends principally on the MCV to determine whether the anemia is microcytic, normocytic, or macrocytic, according to the percentile curves of Dallman and Siimes (Figure 30–2).

Although the incidence of IDA in the United States has decreased significantly with improvements in infant nutrition, it remains an important cause of microcytic anemia, especially at ages 6–24 months. A trial of therapeutic iron is appropriate in such children, provided the dietary history is compatible with ID and the physical examination or CBC does not suggest an alternative cause for the anemia. If a trial of therapeutic iron fails to correct the anemia and/or microcytosis, further evaluation is warranted.

Another key element of Figure 30–1 is the use of both the reticulocyte count and the peripheral blood smear to determine whether a normocytic or macrocytic anemia is due to hemolysis. Typically hemolytic disease is associated with an elevated reticulocyte count, but some children with chronic hemolysis initially present during a period of a virus-induced aplasia when the reticulocyte count is not elevated. Thus, review of the peripheral blood smear for evidence of hemolysis (eg, spherocytes, red cell fragmentation, sickle forms) is important in the evaluation of children with normocytic anemias and low reticulocyte counts. When hemolysis is suggested, the correct diagnosis may be suspected by specific abnormalities of red cell morphology or by clues from the history or physical examination. Autoimmune hemolysis is usually excluded by a negative direct antiglobulin test (DAT). Review of blood counts and the peripheral blood smears of the mother and father may suggest genetic disorders such as hereditary spherocytosis. Children with normocytic or macrocytic anemias, with relatively low reticulocyte counts and no evidence of hemolysis on the blood smear, usually have anemias caused by inadequate erythropoiesis in the bone marrow. The presence of neutropenia or thrombocytopenia in such children suggests the possibility of aplastic anemia, malignancy, or severe folate or vitamin B12 deficiency, and usually dictates examination of the bone marrow.

Pure red cell aplasia may be congenital (Diamond-Blackfan anemia), acquired, and transient (transient erythroblastopenia of childhood); a manifestation of a systemic disease such as renal disease or hypothyroidism; or associated with malnutrition or mild deficiencies of folate or vitamin B12.

▲ Figure 30–2. Hemoglobin and red cell volume in infancy and childhood. (Reproduced with permission from Dallman PR, Siimes MA: Percentile curves for hemoglobin and red cell volume in infancy and childhood. J Pediatr 1979 Jan;94(1):26–31.)

PURE RED CELL APLASIA

Infants and children with normocytic or macrocytic anemia, a low reticulocyte count, and normal or elevated numbers of neutrophils and platelets should be suspected of having pure red cell aplasia. Examination of the peripheral blood smear in such cases is important because signs of hemolytic disease suggest chronic hemolysis complicated by an aplastic crisis due to parvovirus infection. Appreciation of this phenomenon is important because chronic hemolytic disease may not be diagnosed until the anemia is exacerbated by an episode of red cell aplasia and subsequent rapidly falling hemoglobin level. In such cases, cardiovascular compromise and congestive heart failure may develop quickly.

1. Congenital Hypoplastic Anemia (Diamond-Blackfan Anemia)

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- **Age:** birth to 1 year.
- **Macrocytic anemia with reticulocytopenia.**
- **Bone marrow with erythroid hypoplasia.**
- **Often short stature or congenital anomalies.**

**General Considerations**

Diamond-Blackfan anemia is a relatively rare cause of anemia that usually presents at 2–3 months of age. To date, mutations of genes encoding ribosomal proteins occurring with autosomal dominance have been recognized. Early diagnosis is important because treatment with corticosteroids results in increased erythropoiesis in 80% of patients, thus avoiding the difficulties and complications of long-term chronic transfusion therapy.

**Clinical Findings**

A. **Symptoms and Signs**

Signs and symptoms are generally those of chronic anemia, such as pallor and congestive heart failure. Jaundice, splenomegaly, or other evidence of hemolysis are usually absent. Short stature or other congenital anomalies are present in 50% of patients. A wide variety of anomalies have been described; craniofacial and triphalangeal thumbs are the most common.

B. **Laboratory Findings**

Diamond-Blackfan anemia is characterized by severe macrocytic anemia and marked reticulocytopenia. The neutrophil count is usually normal or slightly decreased, and the platelet count is normal, elevated, or decreased. The bone marrow usually shows a marked decrease in erythroid precursors but is otherwise normal. In older children, fetal hemoglobin levels are usually increased and there is evidence of persistent fetal erythropoiesis, such as the presence of the i antigen on erythrocytes.

**Differential Diagnosis**

The principal differential diagnosis is transient erythroid aplasia of childhood. Children with Diamond-Blackfan anemia generally present at an earlier age, often have macrocytosis, and have evidence of fetal erythropoiesis and an elevated level of red cell adenosine deaminase. In addition, short stature and congenital anomalies are not associated with transient erythroblastopenia. Last, transient erythroblastopenia of childhood usually resolves within 6–8 weeks of diagnosis, whereas Diamond-Blackfan anemia is a lifelong affliction. Other disorders associated with decreased red cell production such as renal failure, hypothyroidism, and the anemia of chronic disease need to be considered.

**Treatment**

Oral corticosteroids should be initiated at the time of diagnosis. Eight percent of patients respond to prednisone, 2 mg/kg/day, and many who respond subsequently tolerate significant tapering of the dose. Patients who are unresponsive to prednisone require chronic transfusion therapy. Bone marrow transplant is an alternative definitive therapy that should be considered for transfusion-dependent patients who have HLA-identical siblings. Unpredictable spontaneous remissions occur in up to 20% of patients.

**Prognosis**

The prognosis for patients responsive to corticosteroids is generally good, particularly if remission is maintained with low doses of alternate-day prednisone. Patients dependent on transfusion are at risk for the complications of hemosiderosis. There is an increased risk for the development of solid tumors.

2. Transient Erythroblastopenia of Childhood

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Age: 6 months to 4 years.
- Normocytic anemia with reticulocytopenia.
- Absence of hepatosplenomegaly or lymphadenopathy.
- Erythroid precursors initially absent from bone marrow.

**General Considerations**

Transient erythroblastopenia of childhood is a relatively common cause of acquired anemia in early childhood. The disorder is suspected when a normocytic anemia is discovered during evaluation of pallor or when a CBC is obtained for another reason. Because the anemia is due to decreased red cell production, and thus develops slowly, the cardiovascular system has time to compensate. Therefore, children with hemoglobin levels as low as 4–5 g/dL may look remarkably well. The disorder is thought to be autoimmune in most cases, because IgG from some patients has been shown to suppress erythropoiesis in vitro.

**Clinical Findings**

Pallor is the most common sign, and hepatosplenomegaly and lymphadenopathy are absent. The anemia is normocytic, and the peripheral blood smear shows no evidence of hemolysis. The platelet count is normal or elevated, and the neutrophil count is normal or, in some cases, decreased. Early in the course, no reticulocytes are identified. The Coombs test is negative, and there is no evidence of chronic renal disease, hypothyroidism, or other systemic disorder. Bone marrow examination shows severe erythroid hypoplasia initially; subsequently, erythroid hyperplasia develops along with reticulocytosis, and the anemia resolves.

**Differential Diagnosis**

Transient erythroblastopenia of childhood must be differentiated from Diamond-Blackfan anemia, particularly in infants younger than 1 year. In contrast to Diamond-Blackfan anemia, transient erythroblastopenia is not associated with macrocytosis, short stature, or congenital anomalies, or with evidence of fetal erythropoiesis prior to the phase of recovery. Also in contrast to Diamond-Blackfan anemia, transient erythroblastopenia is associated with normal levels of red cell adenosine deaminase. Transient erythroblastopenia of childhood must also be differentiated from chronic disorders associated with decreased red cell production, such as renal failure, hypothyroidism, and other chronic states of infection or inflammation. As with other single cytopenias, the possibility of malignancy (ie, leukemia) should always be considered, particularly if fever, bone pain, hepatosplenomegaly, or lymphadenopathy is present. In such cases, examination of the bone marrow is generally diagnostic. Confusion may sometimes arise when the anemia of transient erythroblastopenia is first identified during the early phase of recovery when the reticulocyte count is high. In such cases, the disorder may be confused with the anemia of acute blood loss or with hemolytic disease. In contrast to hemolytic disorders, transient erythroblastopenia of childhood is not associated with jaundice or peripheral destruction of red cells.

**Treatment & Prognosis**

By definition, this is a transient disorder. Some children require red cell transfusions if cardiovascular compromise is present. Resolution of the anemia is heralded by an increase in the reticulocyte count, which generally occurs within 4–8 weeks of diagnosis. Transient erythroblastopenia of childhood is not treated with corticosteroids because of its short course.

**NUTRITIONAL ANEMIAS**

1. Iron-Deficiency Anemia

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Pallor and fatigue.
- Poor dietary intake of iron (ages 6–24 months).
- Chronic blood loss (age > 2 years).
- Microcytic hypochromic anemia.

**General Considerations**

Iron deficiency (ID) and iron deficiency anemia (IDA) are a worldwide concern. ID is defined as a state in which there is insufficient iron to maintain normal physiologic functions such that iron stores (serum ferritin or bone marrow iron content) are reduced. IDA is defined as a hemoglobin more than two standard deviations below normal for age and gender, which has developed as a consequence of ID.

Normal-term infants are born with sufficient iron stores to prevent ID for the first 4 months of life, whereas premature infants have reduced iron stores since iron is predominantly acquired in the last trimester. Thus
premature infants, as well as those with low birth weight, neonatal anemia, perinatal blood loss, or subsequent hemorrhage may have reduced iron stores. Breast milk is low in iron relative to cow’s milk and fortified formulas, and without iron supplementation, ID may develop in exclusively breast-fed children.

» **Clinical Findings**

**A. Symptoms and Signs**

Symptoms and signs vary with the severity of the deficiency. ID is usually asymptomatic. IDA may be associated with pallor, fatigue, and irritability. A history of pica is common. It is controversial whether or not ID/IDA adversely affects long-term neurodevelopment and behavior. IDA is associated with increased lead absorption and subsequent neurotoxicity.

**B. Laboratory Findings**

According to the American Academy of Pediatrics (AAP) guidelines, screening for anemia should be performed at about 12 months of age with determination of hemoglobin concentration and an assessment of risk factors for ID/IDA. Risks include low socioeconomic status, prematurity or low birth weight, lead exposure, exclusive breast-feeding beyond 4 months of age without iron supplementation, weaning to whole milk or complementary foods that do not include iron, feeding problems, poor growth, and inadequate nutrition. If the hemoglobin is less than 11 mg/dL or there is a high risk for ID, an iron evaluation should be performed. There is no single measurement that will document the iron status; recommended tests include serum ferritin, C-reactive protein, reticulocyte hemoglobin concentration.

» **Differential Diagnosis**

The differential diagnosis is that of microcytic, hypochromic anemia. The possibility of thalassemia (α-thalassemia, β-thalassemia, and hemoglobin E disorders) should be considered, especially in infants of African, Mediterranean, or Asian ethnic background. In contrast to infants with ID, those with thalassemia generally have an elevated red cell number and are less likely, in mild cases, to have an elevated RBC distribution width (the Mentzer index of the MCV divided by the red cell number is usually < 13 in thalassemia). Thalassemias are associated with normal or increased levels of serum iron and ferritin and with normal iron-binding capacity. The hemoglobin electrophoresis in β-thalassemia minor typically shows an elevation of hemoglobin A₂ levels, but coexistent ID may theoretically lower the percentage of hemoglobin A₂ into the normal range. Hemoglobin electrophoresis will also identify children with hemoglobin E, a cause of microcytosis common in Southeast Asians.

In contrast, the hemoglobin electrophoresis in α-thalassemia trait is normal. Lead poisoning has also been associated with microcytic anemia, but anemia with lead levels less than 40 mg/dL is often due to coexistent ID.

The anemia of chronic inflammation or infection is normocytic but in late stages may be microcytic. This anemia is usually suspected because of the presence of a chronic systemic disorder and an elevated CRP. Relatively mild infections, particularly during infancy, may cause transient anemia. Thus, screening tests for anemia should not be obtained within 3–4 weeks of such infections.

**2. Megaloblastic Anemias**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Pallor and fatigue.
- Nutritional deficiency or intestinal malabsorption.
- Macrocytic anemia.
- Megaloblastic bone marrow changes.
General Considerations

Megaloblastic anemia is a macrocytic anemia caused by deficiency of cobalamin (vitamin B₁₂), folic acid, or both. Cobalamin deficiency due to dietary insufficiency may occur in infants who are breast-fed by mothers who are vegans or who have pernicious anemia. Intestinal malabsorption is the usual cause of cobalamin deficiency in children and occurs with Crohn disease, chronic pancreatitis, bacterial overgrowth of the small bowel, infection with the fish tapeworm (Diphyllobothrium latum), or after surgical resection of the terminal ileum. Deficiencies due to inborn errors of metabolism (transcobalamin II deficiency and methylmalonic aciduria) also have been described. Malabsorption of cobalamin due to deficiency of intrinsic factor (pernicious anemia) is rare in childhood.

Folic acid deficiency may be caused by inadequate dietary intake, malabsorption, increased folate requirements, or some combination of the three. Folate deficiency due to dietary deficiency alone is rare but occurs in severely malnourished infants and has been reported in infants fed goat's milk not fortified with folic acid. Folic acid is absorbed in the jejunum, and deficiencies are encountered in malabsorptive syndromes such as celiac disease. Anticonvulsant medications (eg, phenytoin and phenobarbital) and cytotoxic drugs (eg, methotrexate) also have been associated with folate deficiency, caused by interference with folate absorption or metabolism. Finally, folic acid deficiency is more likely to develop in infants and children with increased requirements. This occurs during infancy because of rapid growth and also in children with chronic hemolytic anemia. Premature infants are particularly susceptible to the development of the deficiency because of low body stores of folate.

Clinical Findings

A. Symptoms and Signs

Infants with megaloblastic anemia may show pallor and mild jaundice as a result of ineffective erythropoiesis. Classically, the tongue is smooth and beefy red. Infants with cobalamin deficiency may be irritable and may be poor feeders. Older children with cobalamin deficiency may complain of paresthesias, weakness, or an unsteady gait, and may show decreased vibratory sensation and proprioception on neurologic examination.

B. Laboratory Findings

The laboratory findings of megaloblastic anemia include an elevated MCV and mean corpuscular hemoglobin (MCH). The peripheral blood smear shows numerous macro-ovalocytes with anisocytosis and poikilocytosis. Neutrophils are large and have hypersegmented nuclei. The white cell and platelet counts are normal with mild deficiencies but may be decreased in more severe cases. Examination of the bone marrow is not indicated, but it typically shows erythroid hyperplasia with large erythroid and myeloid precursors. Nuclear maturation is delayed compared with cytoplasmic maturation, and erythropoiesis is ineffective. The serum indirect bilirubin concentration may be slightly elevated.

Children with cobalamin deficiency often have a low serum vitamin B₁₂ level, but not always. Decreased levels of serum vitamin B₁₂ may also be found in about 30% of patients with folic acid deficiency. Negative results should not negate treatment if clinically compatible symptoms are present. The level of red cell folate is a better reflection of folate stores than is the serum folic acid level. Elevated serum levels of metabolic intermediates (methylmalonic acid and homocysteine) may help establish the correct diagnosis. Elevated methylmalonic acid levels are consistent with cobalamin deficiency and generally decrease with treatment, whereas elevated levels of homocysteine occur with both cobalamin and folate deficiency as well as hypothyroidism.

Differential Diagnosis

Most macrocytic anemias in pediatrics are not megaloblastic. Other causes of an increased MCV include drug therapy (eg, anticonvulsants, anti-HIV nucleoside analogues), Down syndrome, an elevated reticulocyte count (hemolytic anemias), bone marrow failure syndromes (Fanconi anemia, Diamond-Blackfan anemia), liver disease, and hypothyroidism.

Treatment

Treatment of cobalamin deficiency due to inadequate dietary intake is readily accomplished with high-dose oral supplementation that is as effective as parenteral treatment if absorption is normal. Folic acid deficiency is treated effectively with oral folic acid in most cases. Children at risk for the development of folic acid deficiencies, such as premature infants and those with chronic hemolysis, are often given folic acid prophylactically.

ANEMIA OF CHRONIC DISORDERS

Anemia is a common manifestation of many chronic illnesses in children. In some instances, causes may be mixed. For example, children with chronic disorders involving intestinal malabsorption or blood loss may have anemia of chronic inflammation in combination with nutritional deficiencies of iron, folate, or cobalamin. In other settings, the anemia is due to dysfunction of a single organ (eg, renal
failure, hypothyroidism), and correction of the underlying abnormality resolves the anemia.

1. Anemia of Chronic Inflammation

Anemia is frequently associated with chronic infections or inflammatory diseases. The anemia is usually mild to moderate in severity, with a hemoglobin level of 8–12 g/dL. In general, the severity of the anemia corresponds to the severity of the underlying disorder, and there may be microcytosis, but not hypochromia. The reticulocyte count is low. The anemia is thought to be due to inflammatory cytokines that inhibit erythropoiesis, and shunting of iron into, and impaired iron release from, reticuloendothelial cells. High levels of hepcidin, a peptide produced in the liver during infection or inflammation, reduce iron absorption by the duodenum and release from macrophages. Levels of erythropoietin are relatively low for the severity of the anemia. The serum iron concentration is low, but in contrast to ID, anemia of chronic inflammation is not associated with elevated iron-binding capacity and is associated with an elevated serum ferritin level. Treatment consists of correction of the underlying disorder, which, if controlled, generally results in improvement in hemoglobin level.

2. Anemia of Chronic Renal Failure

Severe normocytic anemia occurs in most forms of renal disease that have progressed to renal insufficiency. Although white cell and platelet production remain normal, the bone marrow shows significant hypoplasia of the erythroid series and the reticulocyte count is low. The principal mechanism is deficiency of erythropoietin, a hormone produced in the kidney, but other factors may contribute to the anemia. In the presence of significant uremia, a component of hemolysis may also be present. Recombinant human erythropoietin (epoetin alfa) and iron correct the anemia, largely eliminating the need for transfusions.

3. Anemia of Hypothyroidism

Some patients with hypothyroidism develop significant anemia. Occasionally, anemia is detected before the diagnosis of the underlying disorder. A decreased growth velocity in an anemic child suggests hypothyroidism. The anemia is usually normocytic or macrocytic, but it is not megaloblastic and, hence not due to deficiencies of cobalamin or folate. Replacement therapy with thyroid hormone is usually effective in correcting the anemia.

1. Hereditary Spherocytosis

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Anemia and jaundice.
- Splenomegaly.
- Positive family history of anemia, jaundice, or gallstones in 75%
- Spherocytosis with increased reticulocytes.
- Increased osmotic fragility.
- Negative DAT.

**General Considerations**

Hereditary spherocytosis is a relatively common inherited hemolytic anemia that occurs in all ethnic groups, but is most common in Caucasians of northern European ancestry, in whom the incidence is about 1:2000-5000. The disorder is marked by variable degrees of anemia, jaundice, and splenomegaly. In most persons, the disorder is mild to moderate because erythroid hyperplasia fully or partially compensates for hemolysis. The hallmark of hereditary spherocytosis is the presence of microspherocytes in the peripheral blood. The disease is inherited in an autosomal dominant fashion in about 75% of cases; the remaining cases are thought to be autosomal recessive or due to de novo mutations. Hereditary spherocytosis is secondary to alteration of genes encoding for spectrin, band 3, ankyrin, or protein 4.2 of the red cell membrane; spectrin abnormalities are more
often diagnosed in childhood and band 3 in adulthood. The vertical linkages in the membrane are impaired so that spherocytes form. These are poorly deformable, resulting in a shortened lifespan because they are trapped in the microcirculation of the spleen and engulfed by splenic macrophages.

**Clinical Findings**

**A. Symptoms and Signs**

Hemolysis causes significant neonatal hyperbilirubinemia in 50% of affected children. Splenomegaly subsequently develops in the majority and is often present by age 5 years. Jaundice is variably present and in many patients may be noted only during infection. Patients with significant chronic anemia may complain of pallor, fatigue, or malaise. Intermittent exacerbations of the anemia are caused by increased hemolysis, splenic sequestration or by aplastic crises, and may be associated with severe weakness, fatigue, fever, abdominal pain, or even heart failure.

**B. Laboratory Findings**

Most patients have mild chronic hemolysis with hemoglobin levels of 9–12 g/dL. In some cases, the hemolysis is fully compensated and the hemoglobin level is in the normal range. Rare cases of severe disease require frequent transfusions. The anemia is usually normocytic and hyperchromic, and many patients have an elevated MCHC and RDW. The peripheral blood smear shows numerous microspherocytes and polychromasia. The reticulocyte count is elevated, often higher than might be expected for the degree of anemia. WBC and platelet counts are usually normal. Serum bilirubin usually shows an elevation in the unconjugated fraction. The DAT is negative. The osmotic fragility is increased, particularly after incubation at 37°C for 24 hours and confirms the diagnosis. An alternative confirmatory test is the eosin-5’-maleinide binding test (EMA).

**Differential Diagnosis**

Spherocytes are frequently present in persons with immune hemolysis. Thus, in the newborn, hereditary spherocytosis must be distinguished from hemolytic disease caused by ABO or other blood type incompatibilities. Older patients with autoimmune hemolytic anemia (AIHA) frequently present with jaundice, splenomegaly, and spherocytes on the peripheral blood smear. The DAT is positive in most cases of immune hemolysis and negative in hereditary spherocytosis. Occasionally, the diagnosis is confused in patients with splenomegaly from other causes, especially when hypersplenism increases red cell destruction and when some spherocytes are noted on the blood smear. In such cases, the true cause of the splenomegaly may be suggested by signs or symptoms of portal hypertension or by laboratory evidence of chronic liver disease. In contrast to children with hereditary spherocytosis, those with hypersplenism typically have some degree of thrombocytopenia or neutropenia.

**Complications**

Severe jaundice may occur in the neonatal period and, if not controlled by phototherapy, may occasionally require exchange transfusion. Gallstones occur in 60%–70% of adults who have not undergone splenectomy and may form as early as age 5–10 years. Intermittent or persistent splenomegaly occurs in 10%–25% of patients and may require removal. Splenectomy is associated with an increased risk of overwhelming bacterial infections, particularly with pneumococci.

**Treatment**

Supportive measures include the administration of folic acid to prevent the development of red cell hypoplasia due to folate deficiency. Acute hemolytic or aplastic crises caused by infection, often with human parvovirus, may be severe enough to require red cell transfusions. Laparoscopic splenectomy, if possible, may be indicated depending on clinical severity. Splenectomy increases survival of the red cells and results in complete correction of the anemia in most cases. Except in unusually severe cases, the procedure should be postponed until the child is at least age 5 years because of the greater risk of postsplenectomy sepsis prior to this age. All patients scheduled for splenectomy should be immunized, ideally at least 2 weeks prior, with pneumococcal, *Haemophilus influenzae* type b (Hib), and meningococcal vaccines. and prophylactic antimicrobial therapy, usually penicillin, is recommended by the RED BOOK for asplenic children younger than 5 years of age and for at least 1 year after splenectomy at any age. High-risk patients with asplenia could continue prophylaxis throughout childhood and into adulthood.

Asplenic patients with fever should be promptly evaluated for sepsis. Splenectomy prevents the subsequent development of cholelithiasis and eliminates the need for the activity restrictions. However, these benefits must be weighed against the risks of the surgical procedure and the subsequent lifelong risk of postsplenectomy sepsis and increased risk for thrombosis.

**Prognosis**

Splenectomy eliminates signs and symptoms in all but the most severe cases. The abnormal red cell morphology and increased osmotic fragility persist without clinical consequence.

### 2. Hereditary Elliptocytosis

Hereditary elliptocytosis is a heterogeneous disorder that ranges in severity from an asymptomatic state with almost normal red cell morphology to about 10% having moderate to severe hemolytic anemia. Most affected persons have numerous elliptocytes on the peripheral blood smear, but...
mild or no hemolysis. Those with hemolysis have an elevated reticulocyte count and may have jaundice and splenomegaly. This disorder is caused by weakened horizontal linkages in the red cell membrane skeleton due to either a defective spectrin dimer-dimer interaction or a defective spectrin-actin protein 4.1R junctional complex. Inheritance is autosomal dominant. Because most patients are asymptomatic, no treatment is indicated. Patients with significant degrees of hemolytic anemia may benefit from folate supplementation or splenectomy but some degree of hemolysis persists post splenectomy.

Some infants with hereditary elliptocytosis present in the neonatal period with moderate to marked hemolysis and significant hyperbilirubinemia. This disorder has been termed transient infantile pyknocytosis because such infants exhibit bizarre erythrocyte morphology with elliptocytes, microspherocytes, and red cell fragments. The MCV is low, and the anemia may be severe enough to require red cell transfusions. Typically, one parent has hereditary elliptocytosis, usually mild or asymptomatic. The infant's hemolysis gradually abates during the first year of life, and the erythrocyte morphology subsequently becomes more typical of hereditary elliptocytosis.

CONGENITAL HEMOLYTIC ANEMIAS: HEMOGLOBINOPATHIES

The hemoglobinopathies are an extremely heterogeneous group of congenital disorders that occur in all ethnic groups. The relatively high frequency of these genetic variants is related to the malaria protection afforded to heterozygous individuals. The hemoglobinopathies are generally classified into two major groups. The first, the thalassemias, are caused by quantitative or qualitative deficiencies in the production of globin chains. The defects in globin synthesis cause microcytic and hypochromic anemias. The second group of hemoglobinopathies consists of those caused by structural abnormalities of globin chains. The most important of these, hemoglobins S, C, and E, are all the result of point mutations and single amino acid substitutions in β-globin. Many, but not all, infants with hemoglobinopathies are identified by routine neonatal screening.

Figure 30–3 shows the normal developmental changes that occur in globin-chain production during gestation and the first year of life. At birth, the predominant hemoglobin is fetal (hemoglobin F), which is composed of two α-globin chains and two γ-globin chains. Subsequently, the production of γ-globin decreases and β-globin increases so that adult hemoglobin (two α and two β globin chains) predominates after 2–4 months of age. Because α-globin chains are present in both fetal and adult hemoglobin, disorders of α-globin synthesis (α-thalassemia) are clinically manifest in the newborn as well as later in life. In contrast, patients with β-globin disorders such as β-thalassemia and sickle cell disease are generally asymptomatic during the first 3–4 months of age.

1. α-Thalassemia

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Predominately African, Mediterranean, Middle Eastern, Chinese, or Southeast Asian ancestry.
- Microcytic, hypochromic anemia of variable severity.
- Generally Bart's hemoglobin (γ4) detected on neonatal screening.

General Considerations

Most of the α-thalassemia syndromes are the result of deletions of one or more of the four α-globin genes on chromosome 16, although nondeletional α+ mutations also occur. Excess non-α-globin chains damage the red cell membrane, causing extravascular hemolysis. The variable severity of the α-thalassemia syndromes is related to the number of gene deletions (Table 30–1). The severity of the α-thalassemia syndromes varies among affected ethnic groups. In persons of African ancestry, α-thalassemia is usually caused by the deletion of only one of the two α-globin genes on each chromosome (trans). Thus, in the African population, heterozygous individuals are silent carriers and homozygous individuals have α-thalassemia trait. In Asians, deletions of one or both α-globin genes on the same chromosome are common (cis); heterozygous individuals are either silent carriers or have α-thalassemia trait, and homozygous individuals or compound heterozygous individuals have α-thalassemia trait, hemoglobin H disease, or hydrops fetalis. Thus, the presence of α-thalassemia in a child of Asian ancestry may have important implications for genetic counseling, whereas this is not usually the case in families of African ancestry.

Clinical Findings

The clinical findings depend on the number of α-globin genes deleted. Table 30–1 summarizes the α-thalassemia syndromes. Persons with three α-globin genes (one-gene deletion) are asymptomatic and have no hematologic abnormalities. Hemoglobin electrophoresis in the neonatal period shows 0%–3% Bart’s hemoglobin, which is a variant hemoglobin composed of four γ-globin chains. Hemoglobin electrophoresis after the first few months of life is normal. Thus, this condition is usually suspected only in the context of family studies or when a small amount of Bart’s hemoglobin is detected by neonatal screening for hemoglobinopathies.

Persons with two α-globin genes (two-gene deletion) are typically asymptomatic. The MCV is usually less than 100 fl at birth. Hematologic studies in older infants and children show a normal or slightly decreased hemoglobin level with a low MCV and a slightly hypochromic blood smear with some target cells.

Persons with one α-globin gene (three-gene deletion) have a mild to moderately severe microcytic hemolytic anemia (hemoglobin level of 7–10 g/dL), which may be accompanied by hepatosplenomegaly and some bony abnormalities caused by the expanded medullary space. The reticulocyte count is elevated, and the red cells show marked hypochromasia and microcytosis with significant poikilocytosis and some basophilic stippling. Incubation of red cells with brilliant cresyl blue shows inclusion bodies formed by denatured hemoglobin H (β₄).

The deletion of all four α-globin genes causes severe intrauterine anemia and results in hydrops fetalis and fetal demise or neonatal death shortly after delivery. Extreme pallor and massive hepatosplenomegaly are present. Hemoglobin electrophoresis reveals a predominance of Bart’s hemoglobin (γ₄) with a complete absence of normal fetal or adult hemoglobin.

*α indicates presence of α-globin gene; — α indicates deletion of α-globin gene.
*N = normal results, Hb = hemoglobin, Hb Bart’s = γ₄, Hb H = β₄.
*The level of Hb Bart’s does not directly correlate with the number of deleted α genes.

Differential Diagnosis

α-Thalassemia trait (two-gene deletion) must be differentiated from other mild microcytic anemias, including ID and β-thalassemia minor (see the next section). In contrast to children with ID, children with α-thalassemia trait have normal or increased levels of ferritin and serum iron. In contrast to children with β-thalassemia minor, children with α-thalassemia trait have a normal hemoglobin electrophoresis after age 4–6 months. Finally, the history of a low MCV (96 fl) at birth or the presence of Bart’s hemoglobin on the neonatal hemoglobinopathy screening test suggests α-thalassemia.

Children with hemoglobin H disease may have jaundice and splenomegaly, and the disorder must be differentiated from other hemolytic anemias. The key to the diagnosis is the decreased MCV and the marked hypochromia on the blood smear. With the exception of β-thalassemia, most other significant hemolytic disorders have a normal or elevated MCV and the RBCs are not hypochromic. Infants with hydrops fetalis due to severe α-thalassemia must be distinguished from those with hydrops due to other causes of anemia, such as alloimmunization or parvovirus.
Complications

The principal complication of α-thalassemia trait is the needless administration of iron, given in the belief that a mild microcytic anemia is due to ID. Persons with hemoglobin H disease may have intermittent exacerbations of their anemia in response to oxidant stress or infection, which occasionally require blood transfusions. Splenomegaly may exacerbate the anemia. Women pregnant with hydropic α-thalassemia fetuses are subject to increased complications of pregnancy, particularly toxemia and postpartum hemorrhage.

Treatment

Persons with α-thalassemia trait require no treatment. Those with hemoglobin H disease should receive supplemental folic acid and avoid the same oxidant drugs that cause hemolysis in persons with G6PD deficiency, because exposure to these drugs may exacerbate their anemia. The anemia may also be exacerbated during periods of infection. Iron-overload may occur independent of whether transfusions are given or not. Hypersplenism may develop later in childhood. Genetic counseling and prenatal diagnosis should be offered to families at risk for hydropic fetuses.

β-Thalassemia

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

β-Thalassemia minor:
► Normal neonatal screening test.
► Predominantly African, Mediterranean, Middle Eastern, or Asian ancestry.
► Mild microcytic, hypochromic anemia.
► No response to iron therapy.
► Elevated level of hemoglobin A2.
β-Thalassemia intermedia:
► Ancestry as above.
► Microcytic, hypochromic anemia that usually becomes symptomatic after the first few years of life with hepatosplenomegaly.

β-Thalassemia major:
► Neonatal screening shows hemoglobin F only.
► Mediterranean, Middle Eastern, or Asian ancestry.
► Severe microcytic, hypochromic anemia with marked hepatosplenomegaly.

General Considerations

In contrast to the four α-globin genes, only two β-globin genes are present, one on each chromosome 11. Excess non-β-globin chains damage the red cells, causing extravascular hemolysis. Individuals heterozygous for one β-thalassemia gene have β-thalassemia minor. Homozygous individuals generally have β-thalassemia major (Cooley anemia), a severe transfusion-dependent anemia. Individuals with β-thalassemia intermedia, which is more severe than thalassemia minor but is not transfusion-dependent, are usually heterozygous for two β+ mutations (produce reduced quantities of normal A hemoglobin) or have both β0 (production of no normal A hemoglobin) and a β+ mutation, or have an alternative mutation such as E in conjunction with a severe β+ or β0 mutation. Thalassemia major is the most common worldwide cause of transfusion-dependent anemia in childhood. In addition, β-thalassemia genes interact with genes for structural β-globin variants, such as hemoglobin S and hemoglobin E to cause serious disease in compound heterozygous individuals. These disorders are discussed further in the sections dealing with sickle cell disease and hemoglobin E disorders.

Clinical Findings

A. Symptoms and Signs

Persons with β-thalassemia minor are usually asymptomatic with a normal physical examination. The time to presentation for those with β-thalassemia intermedia is variable. Those with β-thalassemia major are normal at birth but develop significant anemia during the first year of life. If the disorder is not identified and treated with blood transfusions, such children grow poorly and develop massive hepatosplenomegaly and enlargement of the medullary space with thinning of the bony cortex. The skeletal changes (due to ineffective erythropoiesis and marrow hyperplasia) cause characteristic facial deformities (prominent forehead and maxilla) and predispose the child to pathologic fractures.

B. Laboratory Findings

Children with β-thalassemia minor have normal neonatal screening results but subsequently develop a decreased MCV with or without mild anemia. The peripheral blood smear
typically shows hypochromia, target cells, and sometimes basophilic stippling. Hemoglobin electrophoresis performed after 6–12 months of age is usually diagnostic when levels of hemoglobin A₂, hemoglobin F, or both are elevated. β-Thalassemia major is often initially suspected when hemoglobin A is absent on neonatal screening. Such infants are hematologically normal at birth, but they develop severe anemia after the first few months of life. The peripheral blood smear typically shows a severe hypochromic, microcytic anemia with marked anisocytosis and poikilocytosis. Target cells are prominent, and nucleated RBCs often exceed the number of circulating WBCs. The hemoglobin level usually falls to 5–6 g/dL or less, and the reticulocyte count is elevated. Platelet and WBC counts may be increased, and the serum indirect bilirubin level is elevated. The bone marrow shows marked erythroid hyperplasia, but this finding is not needed for diagnosis. Hemoglobin electrophoresis shows only fetal hemoglobin and hemoglobin A₁ in children with homozygous β⁰-thalassemia. Those with β^+-thalassemia genes make a variable amount of hemoglobin A, depending on the mutation, but have a marked increase in fetal and hemoglobin A₂ levels. The diagnosis of β-thalassemia major, intermedia or minor, can be supported by DNA analysis.

**Differential Diagnosis**

β-Thalassemia minor must be differentiated from other causes of mild microcytic, hypochromic anemias, principally ID and α-thalassemia. In contrast to patients with IDA, those with β-thalassemia minor typically have an elevated number of RBCs, and the Mentzer index of the MCV divided by the red cell count is under 13. Generally, an elevated hemoglobin A₂ level is diagnostic; occasionally, the A₂ level may be lower by coexistent ID.

β-Thalassemia major is rarely confused with other disorders. Hemoglobin electrophoresis, DNA analysis and family studies readily distinguish it from hemoglobin E/β-thalassemia, which is the other increasingly important cause of transfusion-dependent thalassemia.

**Complications**

The principal complication of β-thalassemia minor is the unnecessary use of iron therapy in a futile attempt to correct the microcytic anemia. Children with β-thalassemia major who are inadequately transfused experience poor growth and recurrent infections and may have hepatosplenomegaly, thinning of the cortical bone, and pathologic fractures. Without treatment, most children die within the first decade of life. The principal complications of β-thalassemia major in transfused children are hemosiderosis, splenomegaly, and hypersplenism. Transfusion-related hemosiderosis requires chelation therapy to minimize cardiac, hepatic, and endocrine dysfunction. Noncompliance with chelation in adolescents and young adults may lead to death from congestive heart failure, cardiac arrhythmias, or hepatic failure. Even with adequate transfusions, many patients develop splenomegaly and some degree of hypersplenism. Splenectomy increases the risk of thrombosis, pulmonary hypertension, and overwhelming sepsis.

**Treatment**

β-Thalassemia minor requires no specific therapy, but the diagnosis may have important genetic implications for the family. The time to presentation for those with β-thalassemia intermedia is variable. For β-thalassemia major, two treatments are available: chronic transfusion with iron chelation and hematopoietic stem cell transplant. Programs of blood transfusion are generally targeted to maintain a nadir hemoglobin level of 9–10 g/dL. This approach gives increased vigor and well-being, improved growth, and fewer overall complications. However, maintenance of good health requires iron chelation. Small doses of supplemental ascorbic acid may enhance the efficacy of iron chelation. Patients who undergo splenectomy to reduce transfusion requirements, and hence iron loading, should receive vaccines against encapsulated organisms prior to the procedure and be instructed in the use of prophylactic penicillin and to seek urgent treatment of all febrile illness after splenectomy.

Hematopoietic stem cell transplant is an important therapeutic option for children with β-thalassemia major. The probability of hematologic cure with an HLA-matched related donor is greater than 90% when transplant is performed prior to the development of hepatomegaly or portal fibrosis. Gene therapy is becoming an alternative option.

### 3. Sickle Cell Disease

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Neonatal screening test usually with hemoglobins F, FSC, or FSA (S > A).
- Predominantly African, Mediterranean, Middle Eastern, Indian, or Caribbean ancestry.
- Anemia, elevated reticulocyte count, usually jaundice.
- Recurrent episodes of musculoskeletal or abdominal pain.
- Often hepatomegaly and splenomegaly that resolves.
- Increased risk of bacterial sepsis.
### General Considerations
Sickle cell disease encompasses a family of disorders with manifestations secondary to the propensity of deoxygenated sickle hemoglobin (S) to polymerize. Polymerization of sickle hemoglobin distorts erythrocyte morphology; decreases red cell deformability; causes a marked reduction in red cell lifespan; increases blood viscosity; and predisposes to inflammation, coagulation activation, and episodes of vaso-occlusion. Sickle cell anemia, the most severe sickling disorder, is caused by homozygosity for the sickle gene and is the most common form of sickle cell disease. Other clinically important sickling disorders are compound heterozygous conditions in which the sickle gene interacts with genes for hemoglobins C, E, D\textsubscript{Punjab}, O\textsubscript{Arab}, C\textsubscript{Harlem}, or \(\beta\)-thalassemia.

Overall, sickle cell disease occurs in about 1 of every 400 African-American infants. Eight percent of African Americans are heterozygous carriers of the sickle gene and thus have sickle cell trait.

### Clinical Findings
#### A. Symptoms and Signs
These are related to the hemolytic anemia, tissue ischemia, and organ dysfunction caused by vaso-occlusion. They are most severe in children with sickle cell anemia or sickle \(\beta^0\)-thalassemia. Physical findings are normal at birth, and symptoms are unusual before age 3–4 months because high levels of fetal hemoglobin inhibit sickling. A moderately severe hemolytic anemia may be present by age 1 year. This causes pallor, fatigue, and jaundice, and predisposes to the development of gallstones during childhood and adolescence. Intense congestion of the spleen with sickled cells may cause splenomegaly in early childhood and ultimately results in functional asplenia as early as age 3 months in sickle cell anemia. This places children at great risk for overwhelming infection with encapsulated bacteria, particularly pneumococci. Up to 30% of patients experience one or more episodes of acute splenic sequestration, characterized by sudden enlargement of the spleen with pooling of red cells, acute exacerbation of anemia, and, in severe cases, shock and death. Acute exacerbation of anemia also occurs with aplastic crises, usually caused by infection with human parvovirus B19 and other viruses.

Recurrent episodes of vaso-occlusion and tissue ischemia cause acute and chronic morbidity. Dactylitis, or hand-and-foot syndrome, is the most common initial symptom of the disease and occurs in up to 50% of children with sickle cell anemia before age 3 years. Recurrent episodes of abdominal and musculoskeletal pain may occur throughout life. Historically, overt strokes occurred in about 11% of children with sickle cell anemia and without chronic transfusion tended to be recurrent; recurrence is significantly reduced with chronic red cell transfusions. The acute chest syndrome, characterized by respiratory symptoms and a new acute pulmonary infiltrate, is caused by pulmonary infection, infarction, or fat embolism from ischemic bone marrow. All tissues are susceptible to damage from vaso-occlusion, and multiple organ dysfunction is common by adulthood in those with sickle cell anemia or sickle \(\beta^0\)-thalassemia. The common manifestations of sickle cell disease are listed in Table 30–2. Manifestations are less frequent in those with SC and \(S\ \beta^+\)-thalassemia.

### B. Laboratory Findings
Children with sickle cell anemia generally show a baseline hemoglobin level of 7–10 g/dL. This value may fall to life-threatening levels at the time of a splenic sequestration or aplastic crisis; often this occurs in association with parvovirus B19 infection. The baseline reticulocyte count is elevated. The anemia is usually normocytic or macrocytic, and the peripheral blood smear typically shows the characteristic sickle cells as well as numerous target cells. Patients with sickle \(\beta\)-thalassemia have a low MCV and hypochromia. Those with sickle \(\beta^+\)-thalassemia tend to have less hemolysis and anemia. Persons with sickle hemoglobin

\(\textsuperscript{a}\)Associated with significant mortality rate.
C disease have fewer sickle forms and more target cells, and the hemoglobin level may be normal or only slightly decreased because the rate of hemolysis is much less than in sickle cell anemia.

Most infants with sickle hemoglobinopathies born in the United States are identified by universal neonatal screening. Results indicative of possible sickle cell disease require prompt confirmation. Children with sickle cell anemia and with sickle β+-thalassemia have only hemoglobins S, F, and A₂. Persons with sickle β¹-thalassemia have a preponderance of hemoglobin S with a lesser amount of hemoglobin A and elevated A₂. Persons with sickle hemoglobin C disease have about equal amounts of hemoglobins S and C although the quantity of S is greater than the C. The use of solubility tests to screen for the presence of sickle hemoglobin should be avoided because a positive result does not differentiate sickle cell trait from sickle cell disease. Solubility tests will not identify hemoglobin variants other than S. Thus, hemoglobin electrophoresis, HPLC or DNA analysis is always necessary to accurately identify sickle cell disease.

**Differential Diagnosis**

Hemoglobin electrophoresis and sometimes hematologic studies of the parents are usually sufficient to confirm sickle cell disease, although DNA testing is available. It is critical to determine whether the child with only F and S hemoglobins on newborn screening has sickle cell anemia, sickle β⁰-thalassemia, or is a compound heterozygote for sickle hemoglobin and pancellular hereditary persistence of fetal hemoglobin. Such children, when older, typically have 30% fetal hemoglobin and 70% hemoglobin S, and are well.

**Complications**

Repeated tissue ischemia and infarction can cause damage to virtually every organ system. Table 30–2 lists the most important complications. Patients who require frequent red cell transfusions are at risk of developing transfusion-related hemosiderosis and infections as well as red cell antibodies. Guidelines for routine evaluation for stroke risk with transcranial doppler screening are available followed by red cell transfusion and possibly hydroxyurea has reduced the incidence of stroke.

**Treatment**

The cornerstone of treatment is enrollment in a sickle cell program involving patient and family education, comprehensive outpatient care, and appropriate treatment of acute complications. Important to the success of such a program are psychosocial services, blood bank services, and the ready availability of baseline patient information in the setting in which acute illnesses are evaluated and treated.

Management of sickle cell anemia and sickle β⁰-thalassemia includes daily prophylactic penicillin, which should be initiated by age 2 months and continued to age 5 years. The routine use of penicillin prophylaxis in sickle hemoglobin C disease and sickle β¹-thalassemia is controversial. Pneumococcal conjugate and polysaccharide vaccines should be administered to all children who have sickle cell disease. Other routine immunizations, including yearly vaccination against influenza, should be provided. All illnesses associated with fever greater than 38.5°C should be evaluated promptly, bacterial cultures performed, parenteral broad-spectrum antibiotics administered, and careful inpatient or outpatient observation conducted.

Treatment of painful vaso-occlusive episodes includes the maintenance of adequate hydration (with avoidance of overhydration), correction of acidosis if present, administration of adequate analgesia, maintenance of normal oxygen saturation, and the treatment of any associated infections.

Red cell transfusions play an important role in management. Transfusions are indicated to improve oxygen-carrying capacity during acute severe exacerbations of anemia, as occurs during episodes of splenic sequestration or aplastic crisis. Red cell transfusions are not indicated for the treatment of chronic steady-state anemia or for uncomplicated episodes of vaso-occlusive pain. Simple or partial exchange transfusion to reduce the percentage of circulating sickle cells is indicated for some acute events and may be lifesaving. These events include stroke, moderate to severe acute chest syndrome, and multi-organ failure. Transfusions may be administered prior to high-risk procedures such as surgery with general anesthesia and arteriograms with high ionic contrast materials. Some patients with severe complications may benefit from chronic transfusion therapy. The most common indications for transfusions are stroke or an abnormal transcranial Doppler assessment indicating an increased risk for stroke. Matching for red cell antigens or giving red cells negative for C, E, and Kell antigens reduces the incidence of alloimmunization.

Successful hematopoietic stem cell transplant can cure sickle cell disease, but to date its use has been limited because of the risks associated with the procedure, the inability to predict disease severity, and the paucity of HLA-identical sibling donors. Daily administration of oral hydroxyurea increases levels of fetal hemoglobin, decreases hemolysis, and reduces the frequency of acute chest syndrome, hospitalization rates, and need for transfusions. The hematologic effects and short-term toxicity of hydroxyurea in children are similar to those in adults. Hydroxyurea is recommended for children and adolescents with sickle cell anemia and sickle β⁰-thalassemia; efficacy in SC and β¹-thalassemia has not been formally studied.
**Prognosis**

Early identification by neonatal screening, combined with sickle cell comprehensive care that includes prescription of prophylactic penicillin, instruction on splenic palpation, and education on the need to urgently seek care when fever occurs, has markedly reduced mortality in childhood. Most patients now live well into adulthood, but eventually succumb to complications with median survival to more than 60 years.

---

**4. Sickle Cell Trait**

Individuals who are heterozygous for the sickle gene have sickle cell trait; neonatal screening that shows hemoglobin FAS (A > S). Adults typically have about 60% hemoglobin A and 40% hemoglobin S. No anemia or hemolysis is present, and the physical examination is normal. Persons with sickle cell trait are generally healthy with normal life expectancy. However, sickle trait erythrocytes are capable of sickling, with acidaemia and hypoxemia. Thus, the kidney may be affected with the most common manifestation of sickle trait being hypostenuria. Transient painless hematuria, usually microscopic, affects about 4% of those with sickle trait and does not progress to significant renal dysfunction. Fewer than 40 individuals have been reported with an exceedingly rare malignancy, renal medullary carcinoma, and the majority have had sickle trait. The incidence of bacteriuria and pyelonephritis may be increased during pregnancy, but overall rates of maternal and infant morbidity and mortality are not affected by sickle cell trait.

Exertion at moderate altitudes rarely precipitates splenic infarction. In general, exercise tolerance seems to be normal; the incidence of sickle cell trait in black professional football players is similar to that of the general African-American population.

There is no reason to restrict strenuous activity for individuals with sickle cell trait. As is true for all individuals performing strenuous activity, it is important to be conditioned, dress appropriately, have access to fluids, rest periodically, and perform moderate activity in extreme heat and humidity. Sickle cell trait is most significant for its genetic implications.

---

**5. Hemoglobin C Disorders**

Hemoglobin C is detected by neonatal screening. Two percent of African Americans are heterozygous for hemoglobin C and thus have hemoglobin C trait. Such individuals have no symptoms, anemia, or hemolysis, but the peripheral blood smear may show some target cells. Identification of persons with hemoglobin C trait is important for genetic counseling, particularly with regard to the possibility of sickle hemoglobin C disease in offspring.

Persons with homozygous hemoglobin C have a mild microcytic hemolytic anemia and may develop splenomegaly. The peripheral blood smear shows prominent target cells. As with other hemolytic anemias, potential complications of homozygous hemoglobin C include gallstones and aplastic crises.

---

**6. Hemoglobin E Disorders**

Hemoglobin E is the second most common hemoglobin variant worldwide, with a gene frequency up to 60% in northeast Thailand and Cambodia. Persons heterozygous for hemoglobin E show hemoglobin FAE by neonatal screening and are asymptomatic and usually not anemic, but they may have mild microcytosis. Individuals homozygous for hemoglobin E are also asymptomatic but may have mild anemia; the peripheral blood smear shows microcytosis and some target cells.

Compound heterozygotes for hemoglobin E and β0-thalassemia are normal at birth and, like infants with homozygous E, show hemoglobin FE on neonatal screening. Unlike homozygotes, they subsequently develop mild to severe microcytic hypochromic anemia. Such children may exhibit jaundice, hepatosplenomegaly, and poor growth if the disorder is not recognized and treated appropriately. In some cases, the anemia becomes severe enough to require lifelong transfusion therapy. Even without regular transfusions, hemosiderosis may occur. In certain areas of the United States, hemoglobin E/β0-thalassemia has become a more common cause of transfusion-dependent anemia than homozygous β-thalassemia.

**7. Other Hemoglobinopathies**

Hemoglobin variants are common. Heterozygous individuals, who are frequently identified during the course of neonatal screening programs, are generally asymptomatic and usually have no anemia or hemolysis. The principal significance of most hemoglobin variants is the potential for disease in compound heterozygous individuals who also inherit thalassemia or sickle hemoglobin. For example, children who are compound heterozygous for hemoglobins S and D (Los Angeles) are symptomatic.

CONGENITAL HEMOLYTIC ANEMIAS:
DISORDERS OF RED CELL METABOLISM

Erythrocytes depend on the anaerobic metabolism of glucose for the maintenance of adenosine triphosphate levels sufficient for homeostasis. Glycolysis also produces the 2,3-diphosphoglycerate (2,3-DPG) levels needed to modulate the oxygen affinity of hemoglobin. Glucose metabolism via the hexose monophosphate shunt is necessary to generate sufficient reduced nicotinamide adenine dinucleotide phosphate (NADPH) and reduced glutathione to protect red cells against oxidant damage. Congenital deficiencies of many glycolytic pathway enzymes have been associated with hemolytic anemias. In general, the morphologic abnormalities present on the peripheral blood smear are nonspecific, and the inheritance of these disorders is autosomal recessive or X-linked. Thus, the possibility of a red cell enzyme defect should be considered during the evaluation of a patient with a congenital hemolytic anemia in the following instances: when the peripheral blood smear does not show red cell morphology typical of membrane or hemoglobin defects (eg, spherocytes, sickle forms, target cells); when hemoglobin disorders are excluded by laboratory results and when family studies are inconsistent. The diagnosis is confirmed by finding a low level of the deficient enzyme. The two most common disorders of erythrocyte metabolism are G6PD deficiency and pyruvate kinase deficiency.

1. Glucose-6-Phosphate Dehydrogenase Deficiency

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Predominantly African, Mediterranean, or Asian ancestry.
- Neonatal hyperbilirubinemia.
- Generally sporadic hemolysis associated with infection or with ingestion of oxidant drugs or fava beans.
- X-linked inheritance.

**General Considerations**

Deficiency of glucose-6-phosphate dehydrogenase (G6PD) is the most common red cell enzyme defect that causes hemolytic anemia. The disorder has an X-linked recessive inheritance and occurs with high frequency among persons of African, Mediterranean, and Asian ancestry. In most instances, the deficiency is due to enzyme instability; thus, older red cells are more deficient than younger ones and are unable to generate sufficient nicotinamide adenine dinucleotide (NADH) to maintain the levels of reduced glutathione necessary to protect the red cells against oxidant stress. Thus, most persons with G6PD deficiency do not have a chronic hemolytic anemia; instead, they have episodic hemolysis at times of exposure to the oxidant stress of infection or of certain drugs or food substances. The severity of the disorder varies among ethnic groups; G6PD deficiency in persons of African ancestry usually is less severe than in other ethnic groups.

**Clinical Findings**

**A. Symptoms and Signs**

Neonates with G6PD deficiency may have significant hyperbilirubinemia and require phototherapy or exchange transfusion to prevent kernicterus. The deficiency is an important cause of hyperbilirubinemia in neonates of Mediterranean or Asian ancestry, but less so in those of African ancestry. Hemolytic episodes are often triggered by infection or by the ingestion of oxidant drugs such as antimalarial compounds, rasburicase, and sulfonamide antibiotics (Table 30–3). Ingestion of fava beans may trigger hemolysis in children of Mediterranean or Asian ancestry but usually not in children of African ancestry. Episodes of hemolysis are associated with pallor, jaundice, hemoglobinuria, and sometimes cardiovascular compromise.

**B. Laboratory Findings**

The hemoglobin concentration, reticulocyte count, and peripheral blood smear are usually normal in the absence of oxidant stress. Episodes of hemolysis are associated with a variable fall in hemoglobin. “Bite” cells or “blister” cells may be seen, along with a few spherocytes on blood smear. Hemoglobinuria is common, and the reticulocyte count increases within a few days. Heinz bodies may be demonstrated with appropriate stains. The diagnosis is confirmed by the finding of reduced levels of G6PD in erythrocytes. Because this enzyme is present in increased quantities in

</tr>
</tbody>
</table>

reticulocytes, the test is best performed at a time when the reticulocyte count is normal or near normal.

**Complications**

Kernicterus is a risk for infants with significant neonatal hyperbilirubinemia. Episodes of acute hemolysis in older children may be life-threatening. Rare G6PD variants are associated with chronic hemolytic anemia; the clinical course of patients with such variants may be complicated by splenomegaly and by the formation of gallstones.

**Treatment**

The most important treatment issue is avoidance of drugs known to be associated with hemolysis (see Table 30–3). For some patients of Mediterranean, Middle Eastern, or Asian ancestry, the consumption of fava beans must also be avoided. Infections should be treated promptly and antibiotics given when appropriate. Most episodes of hemolysis are self-limiting, but red cell transfusions may be lifesaving when signs and symptoms indicate cardiovascular compromise.

2. Pyruvate Kinase Deficiency

Pyruvate kinase deficiency is an autosomal recessive disorder observed in all ethnic groups but is most common in northern Europeans. The deficiency is associated with a chronic hemolytic anemia of varying severity. Approximately one-third of those affected present in the neonatal period with jaundice and hemolysis that require phototherapy or exchange transfusion. Occasionally, the disorder causes hydrops fetalis and neonatal death. In older children, the hemolysis may require red cell transfusions or be mild enough to go unnoticed for many years. Jaundice and splenomegaly frequently occur in the more severe cases. The diagnosis of pyruvate kinase deficiency is occasionally suggested by the presence of echinocytes on the peripheral blood smear, but these findings may be absent prior to splenectomy. The diagnosis depends on the demonstration of low levels of pyruvate kinase activity in red cells.

Treatment of pyruvate kinase depends on the severity of the hemolysis. Blood transfusions may be required for significant anemia, and splenectomy may be beneficial. Although the procedure does not cure the disorder, it ameliorates the anemia and its symptoms. Characteristically, the reticulocyte count increases and echinocytes become more prevalent after splenectomy, despite the decreased hemolysis and increased hemoglobin level.

**ACQUIRED HEMOLYTIC ANEMIA**

1. Autoimmune Hemolytic Anemia

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Pallor, fatigue, jaundice, and dark urine.
- Splenomegaly.
- Positive DAT.
- Reticulocytosis and spherocytosis.

**General Considerations**

Acquired autoimmune hemolytic anemia (AIHA) is rare during the first 4 months of life but is one of the more common causes of acute anemia after the first year. It may arise as a primary disorder or may complicate an infection (hepatitis, upper respiratory tract infections, EBV mononucleosis, or cytomegalovirus [CMV] infection); systemic lupus erythematosus and other autoimmune syndromes; immunodeficiency states, including autoimmune lymphoproliferative syndrome (ALPS); or, very rarely, malignancies. Drugs may induce antibody-associated hemolytic anemia, and recently third-generation cephalosporins, such as ceftriaxone, have become a common cause for this adverse event of antibiotic therapy.

**Clinical Findings**

**A. Symptoms and Signs**

The disease usually has an acute onset manifested by weakness, pallor, dark urine, and fatigue. Jaundice is a prominent finding, and splenomegaly is often present. Some cases have a more chronic, insidious onset. Clinical evidence of an underlying disease may be present.

**B. Laboratory Findings**

The anemia is normochromic and normocytic and may vary from mild to severe (hemoglobin concentration < 5 g/dL). The reticulocyte count and index are usually increased but occasionally are normal or low. Spherocytes and nucleated red cells may be seen on the peripheral blood smear. Although leukocytosis and elevated platelet counts are common, thrombocytopenia occasionally occurs. Other laboratory data observed with hemolysis are increased indirect and total bilirubin, lactic dehydrogenase, aspartate aminotransferase, and urinary urobilinogen. Intravascular hemolysis is indicated by hemoglobinemia, hemoglobinuria,
and decreased levels of haptoglobin. Examination of bone marrow shows marked erythroid hyperplasia and hemophagocytosis, but is seldom required for the diagnosis.

Serologic studies are helpful in defining pathophysiology, planning therapeutic strategies, and assessing prognosis (Table 30–4). In almost all cases, the direct and indirect antiglobulin (DAT and IAT) tests are positive. Further evaluation allows distinction into one of three syndromes. The presence of IgG and no or low level of C3 on the patient’s RBCs, maximal in vitro antibody activity at 37°C, and either no antigen or an Rh-like specificity constitute warm AIHA with mostly extravascular destruction by the reticuloendothelial system. In contrast, the detection of complement alone on RBCs, optimal reactivity at 4°C, and I or i antigen specificity are diagnostic of cold AIHA with mostly intravascular and mild extravascular hemolysis. Cold agglutinins are relatively common (~10%) in normal individuals, but clinically significant cold (IgM) antibodies exhibit in vitro reactivity at 30°C or above.

Paroxysmal cold hemoglobinuria presents a third category of disease. The laboratory evaluation is identical to cold AIHA except for antigen specificity (P) and the exhibition of an in vitro hemolysis. Paroxysmal cold hemoglobinuria is almost always associated with significant infections, such as Mycoplasma, parvovirus, adenovirus, EBV, and CMV.

### Differential Diagnosis

AIHA must be differentiated from other forms of congenital or acquired hemolytic anemias. The DAT discriminates antibody-mediated hemolysis from other causes, such as hereditary spherocytosis. The presence of other cytopenias and antibodies to platelets or neutrophils suggests an autoimmune (eg, lupus) syndrome, immunodeficiency (eg, autoimmune lymphoproliferative syndrome (ALPS), congenital immunodeficiency), or Evans syndrome (AIHA and ITP or other cytopenias associated with autoantibodies). Up to one-third of patients diagnosed as Evans syndrome may have ALPS.

### Complications

The anemia may be very severe and result in cardiovascular collapse, requiring emergency management. The complications of an underlying disease, such as disseminated lupus erythematosus or an immunodeficiency state, may be present.

### Treatment

Medical management of the underlying disease is important in symptomatic cases. Defining the clinical syndrome provides a useful guide to treatment. Most patients (50%–80%) with warm AIHA (in which hemolysis is mostly extravascular)

AIHA, autoimmune hemolytic anemia; IgG, immunoglobulin G; IVIG, intravenous immune globulin; RES, reticuloendothelial system.
respond to prednisone (2 mg/kg/day). After the initial treatment, the dose of corticosteroids may be decreased slowly. Patients may respond to 1 g of intravenous immune globulin (IVIG) per kilogram per day for 2 days, but fewer patients respond to IVIG than to prednisone. In severe cases, rituximab may be a successful alternative; however, this drug should be avoided in AIHA associated with ALPS. Although remission with splenectomy may be as high as 50%–60%, in warm AIHA, this strategy should be considered only for patients older than 5 years who are refractory or resistant to first-line therapies. Short- and long-term complications are now more apparent and include infection with encapsulated organisms, increased risk for venous thromboembolism, and risk for portal and pulmonary arterial hypertension. In cases unresponsive to more conventional therapy, immunosuppressive agents such as cyclophosphamide, azathioprine, mycophenolate mofetil, and corticosteroids may be tried alone or in combination with corticosteroids. The first four therapies produce less myelosuppression and risk for infection and may be helpful when hemolysis is associated with Evans syndrome or ALPS. Plasma exchange is not indicated for warm, IgG, autoantibody diseases. Transplantation, especially when hemolysis is secondary, has been used successfully in small numbers of cases.

Patients with cold AIHA and paroxysmal cold hemoglobinuria are less likely to respond to corticosteroids or IVIG. Because these syndromes are most apt to be associated with infections and have an acute, self-limited course, supportive care alone may be sufficient. Plasma exchange may be effective in severe cold autoimmune (IgM) hemolytic anemia because the offending antibody has an intravascular distribution. Rituximab or other immunosuppressive therapies may be helpful in rare cases.

Supportive therapy is crucial. Patients with cold-reacting antibodies, particularly paroxysmal cold hemoglobinuria, should be kept in a warm environment. Transfusion may be necessary because of the complications of severe anemia but should be used only when there is no alternative. In most patients, cross-match compatible blood will not be found, and the least incompatible unit among the few tested may be transfused. Transfusion must be conducted carefully, beginning with a test dose (see Transfusion Medicine section, later in this chapter). Identification of the patient’s phenotype for minor red cell alloantigens may be helpful in avoiding alloimmunization or in providing appropriate transfusions if alloantibodies arise after initial transfusions. Patients with severe intravascular hemolysis may have associated disseminated intravascular coagulation (DIC), and heparin therapy should be considered in such cases.

Prognosis

The outlook for AIHA in childhood usually is good unless associated diseases are present (eg, likely to have a chronic course).

In general, children with warm (IgG) AIHA are at greater risk for more severe and chronic disease with higher morbidity and mortality rates. Hemolysis and positive antiglobulin tests may continue for months or years. Patients with cold AIHA or paroxysmal cold hemoglobinuria are more likely to have acute, self-limited disease (< 3 months). Paroxysmal cold hemoglobinuria is almost always associated with infection (eg, *Mycoplasma* infection, CMV, and EBV).

### 2. Nonimmune Acquired Hemolytic Anemia

Hepatic disease may alter the lipid composition of the red cell membrane. This usually results in the formation of target cells and is not associated with significant hemolysis.

Occasionally, hepatocellular damage is associated with the formation of spur cells and brisk hemolytic anemia. Renal disease may also be associated with significant hemolysis; hemolytic-uremic syndrome is one example. In this disorder, hemolysis is associated with the presence, on the peripheral blood smear, of echinocytes, helmet cells, fragmented red cells, and spherocytes.

A microangiopathic hemolytic anemia with fragmented red cells and some spherocytes may be observed in several conditions associated with intravascular coagulation and fibrin deposition within vessels. This occurs with DIC complicating severe infection, but may also occur when the intravascular coagulation is localized, as with giant cavernous hemangiomas (Kasabach-Merritt syndrome). Fragmented red cells may also be seen with mechanical damage (eg, associated with artificial heart valves).

### Polycythemia & Methemoglobinemia

Polycythemia in children is defined as a hemoglobin or hematocrit greater than two standard deviations above the normal for age and is usually secondary to chronic hypoxemia. Hereditary polycythemia is rare. The most common cause of secondary polycythemia in children is cyanotic
congenital heart disease, but it also occurs in chronic pulmonary disease such as cystic fibrosis. Persons living at extremely high altitudes, as well as some with methemoglobinemia, develop polycythemia. Polycythemia may occur in the neonatal period; it is particularly exaggerated in infants who are preterm or large for gestational age. It may occur in infants of diabetic mothers, in infants with trisomy 13, 18 or 21 or as a complication of congenital adrenal hyperplasia. The disorder differs from polycythemia vera in that only RBCs are affected; the WBC and platelet counts are normal. There are usually no physical findings except for plethora and splenomegaly. Symptoms are generally limited to headache and lethargy.

ID may complicate polycythemia and aggravate the associated hyperviscosity. This complication of polycythemia should be suspected when the MCV falls below the normal range. Coagulation and bleeding abnormalities, including thrombocytopenia, mild consumption coagulopathy, and elevated fibrinolytic activity, have been described in severely polycythemic cardiac patients. Bleeding at surgery may be severe.

The ideal treatment of secondary polycythemia is correction of the underlying disorder. When this cannot be done, phlebotomy may be necessary to control symptoms. Iron sufficiency should be maintained. These measures help prevent the complications of thrombosis and hemorrhage.

**METHEMOGLOBINEMIA**

When heme iron is oxidized, it changes from the ferrous to the ferric state and methemoglobin is produced. Normally, methemoglobin is enzymatically reduced back to hemoglobin. Methemoglobin is unable to deliver oxygen to the tissues and causes a left shift in the oxygen dissociation curve. Cyanosis is seen with methemoglobin levels greater than 15%.

1. **Hemoglobin M**

This designation is given to several abnormal hemoglobins associated with methemoglobinemia due to amino acid substitutions in the globin chains. Hemoglobin M is transmitted as an autosomal dominant disorder. Hemoglobin electrophoresis at the usual pH will not always demonstrate the abnormal hemoglobin, and isoelectric focusing or DNA analysis may be needed. Affected individuals are cyanotic, but they have normal exercise tolerance and life expectancy. No treatment is indicated.

2. **Congenital Methemoglobinemia Due to Enzyme Deficiencies**

Congenital methemoglobinemia is caused most frequently by deficiency of the reducing enzyme cytochrome b5 reductase and is transmitted as an autosomal recessive trait. Affected individuals may have as much as 40% methemoglobin but usually have no symptoms, although a mild compensatory polycythemia may be present. Patients with diaphorase I deficiency respond to treatment with ascorbic acid and methylene blue (see the next section), but treatment is not usually indicated.

3. **Acquired Methemoglobinemia**

Nitrites and nitrates, chlorates, and quinines such as aniline dyes, sulfonamides, acetanilid, phenacetin, bismuth subnitrate, and potassium chlorate generate methemoglobin. Recreational use of volatile nitrates ("poppers") and cocaine may precipitate methemoglobinemia. Poisoning with a drug or chemical containing one of these substances should be suspected with sudden onset cyanosis. Methemoglobin levels in such cases may be extremely high and can produce anoxia, dyspnea, unconsciousness, circulatory failure, and death. Because of transiently deficient NADH methemoglobin reductase, newborns are more susceptible to drug- or chemical-induced methemoglobinemia especially when exposed to lidocaine, benzocaine, or prilocaine. Infants with metabolic acidosis may also develop methemoglobinemia. Patients with acquired methemoglobinemia (other than those related to G6PD deficiency) respond dramatically to intravenous methylene blue. Ascorbic acid administered orally or intravenously also reduces methemoglobin, but the response is slower.

**DISORDERS OF LEUKOCYTES**

**NEUTROPENIA**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Increased frequency of infections.
- Ulceration of oral mucosa and gingivitis.
- Decreased absolute neutrophil count; normal numbers of red cells and platelets.

**General Considerations**

Neutropenia is an absolute neutrophil (granulocyte) count of less than 1500/μL in childhood, or less than 1100/μL between ages 1 month and 2 years. During the first few days of life, an absolute neutrophil count of less than 3500/μL may be considered neutropenia in term infants. Neutropenia results from absent or defective myeloid stem

Acute severe bacterial or fungal infection is the most significant complication of neutropenia. Although the risk is increased when the absolute neutrophil count is less than 500/μL, the actual susceptibility is variable and depends on the cause of neutropenia, marrow reserves, and other factors. The most common types of infection include septicemia, cellulitis, skin abscesses, pneumonia, and perirectal abscesses. In addition to local signs and symptoms, patients may have chills, fever, and malaise. Sinusitis, aphthous ulcers, gingivitis, and periodontal disease also cause significant problems in chronic neutropenia. In most cases, the spleen and liver are not enlarged. Staphylococcus aureus and gram-negative bacteria are the most common pathogens.

**Clinical Findings**

**A. Symptoms and Signs**

Acute severe bacterial or fungal infection is the most significant complication of neutropenia. Although the risk is increased when the absolute neutrophil count is less than 500/μL, the actual susceptibility is variable and depends on the cause of neutropenia, marrow reserves, and other factors. The most common types of infection include septicemia, cellulitis, skin abscesses, pneumonia, and perirectal abscesses. In addition to local signs and symptoms, patients may have chills, fever, and malaise. Sinusitis, aphthous ulcers, gingivitis, and periodontal disease also cause significant problems in chronic neutropenia. In most cases, the spleen and liver are not enlarged. Staphylococcus aureus and gram-negative bacteria are the most common pathogens.

**B. Laboratory Findings**

Neutrophils are absent or markedly reduced in the peripheral blood. In most forms of neutropenia or agranulocytosis, the monocytes and lymphocytes are normal and the red cells and platelets are not affected. The bone marrow usually shows a normal erythroid series, with adequate megakaryocytes, but a marked reduction in the myeloid cells or a significant delay in maturation of this series may be noted at various stages of myeloid maturation. Total cellularity may be decreased.
In the evaluation of neutropenia (eg, persistent, intermittent, cyclic), attention should be paid to the duration and pattern of neutropenia, the types of infections and their frequency, and phenotypic abnormalities on physical examination. A careful family history and blood counts from the parents may be useful. If an acquired cause, such as viral infection or drug, is not obvious as an acute cause, no other primary disease is present, and the neutropenia is chronic, WBC counts, white cell differential, and platelet and reticulocyte counts should be completed twice weekly for 6 weeks to determine the pattern of neutropenia. Bone marrow aspiration and biopsy including cytogenetic analysis are most important to characterize the morphologic features of myelopoiesis. Measuring the neutrophil counts in response to corticosteroid infusion may document the marrow reserves. Other tests that aid in the diagnosis include measurement of neutrophil antibodies, immunoglobulin levels, antinuclear antibodies, and lymphocyte phenotyping to detect immunodeficiency states. Culture of bone marrow may define myeloid progenitors or the presence of inhibitory factors. Cytokines in plasma or by mononuclear cells can be measured directly. Some neutropenia disorders have abnormal neutrophil function, but severe neutropenia may preclude collection of sufficient cells to complete assays. Analysis for gene mutations noted above may help confirm the diagnosis of a severe neutropenia syndrome. Increased apoptosis in marrow precursors or circulating neutrophils is a general characteristic described in several congenital or genetic disorders.

Treatment

Underlying disorders should be identified and treated or associated agents should be eliminated. Infections should be aggressively assessed and treated. Prophylactic antimicrobial therapy is not indicated for afebrile, asymptomatic patients, but may be considered in rare cases with recurrent infections. Recombinant G-CSF will increase neutrophil counts in most patients; GM-CSF may be considered, but is less extensively used. For patients with neutrophil counts 500/µL or less G-CSF (Filgrastim) may be started at 3–5 mcg/kg/day subcutaneously or intravenously once a day, and the dose adjusted to keep the absolute neutrophil count > 500/µL and < 10,000/µL. The use of long-acting G-CSF (pegfilgrastim) has been used in a few patients with chronic neutropenia. In a small number of patients, G-CSF therapy has been shown to be safe for mothers throughout pregnancies and for newborns without evidence of teratogenicity. Some patients maintain adequate counts with G-CSF given every other day. Treatment will decrease infectious complications but may have little effect on periodontal disease. However, not all patients with neutropenia syndromes require G-CSF (eg, chronic benign neutropenia of childhood). Patients with cyclic neutropenia may have a milder clinical course as they grow older. Immunizations should be given if the adaptive immune system is normal. Hematopoietic stem cell transplant may be considered for patients with severe complications, especially those with severe congenital neutropenia.

Prognosis

The prognosis varies greatly with the cause and severity of the neutropenia. In severe cases with persistent agranulocytosis, the prognosis is poor in spite of antibiotic therapy; in mild or cyclic forms of neutropenia, symptoms may be minimal and the prognosis for normal life expectancy excellent. G-CSF has the potential to prolong life expectancy. Up to 50% of patients with Shwachman syndrome may develop aplastic anemia, myelodysplasia, or leukemia during their lifetime. Patients with other SCNs also have a potential for leukemia, as do patients with neutropenia associated with some immune disorders. Hematopoietic stem cell transplant may be the only curative therapy for some disorders.

NEUTROPHILIA

Neutrophilia is an increase in the absolute neutrophil count in the peripheral blood to greater than 7500–8500/µL for infants, children, and adults. To support the increased peripheral count, neutrophils may be mobilized from bone marrow storage or peripheral marginating pools. Neutrophilia occurs acutely in association with bacterial or viral infections, inflammatory diseases (eg, juvenile rheumatoid arthritis, inflammatory bowel disease, Kawasaki disease), surgical or functional asplenia, liver failure, diabetic ketoacidosis, azotemia, congenital disorders of neutrophil function (eg, chronic granulomatous disease, leukocyte adherence deficiency), and hemolysis. Drugs such as corticosteroids, lithium, and epinephrine increase the blood neutrophil count. Corticosteroids cause release of neutrophils from the marrow pool, inhibit egress from capillary beds, and postpone apoptotic cell death. Epinephrine causes release of the marginating pool. Acute neutrophilia has been reported after stress, such as from electric shock, trauma, burns,
surgery, and emotional upset. Tumors involving the bone marrow, such as lymphomas, neuroblastomas, and rhabdomyosarcoma, may be associated with leukocytosis and the presence of immature myeloid cells in the peripheral blood. Infants with Down syndrome have defective regulation of proliferation and maturation of the myeloid series and may develop neutrophilia. At times this process may affect other cell lines and mimic myeloproliferative disorders or acute leukemia.

The neutrophilias must be distinguished from myeloproliferative disorders such as chronic myelogenous leukemia and juvenile chronic myelogenous leukemia. In general, abnormalities involving other cell lines, the appearance of immature cells on the blood smear, and the presence of hepatosplenomegaly are important differentiating characteristics.

**DISORDERS OF NEUTROPHIL FUNCTION**

Neutrophils play a key role in host defenses. Circulating in the laminar flow of blood vessels, they adhere to capillary vascular endothelium adjacent to sites of infection and inflammation. Moving between endothelial cells, the neutrophil migrates toward the offending agent. Contact with a microbe that is properly opsonized with complement or antibodies triggers ingestion, a process in which cytoplasmic streaming results in the formation of pseudopods that fuse around the invader, encasing it in a phagosome. During the ingestion phase, the oxidase enzyme system assembles in the phagosomal membrane and is activated, taking oxygen from the surrounding medium and reducing it to form toxic oxygen metabolites critical to microbicidal activity. Concurrently, granules from the two main classes (azurophil and specific) fuse and release their contents into the phagolysosome. The concentration of toxic oxygen metabolites (eg, hydrogen peroxide, hypochlorous acid, hydroxyl radical) and other compounds (eg, proteases, cationic proteins, cathespins, defensins) increases dramatically, resulting in the death and dissolution of the microbe. Complex physiologic and biochemical processes support and control these functions. Defects in any of these processes may lead to inadequate cell function and an increased risk of infection.

**Clinical Findings**

Recurrent bacterial or fungal infections are the hallmark of neutrophil dysfunction. Although patients will have infection-free periods, episodes of pneumonia, sinusitis, cellulitis, cutaneous and mucosal infections (including perianal or peritonsillar abscesses), and lymphadenitis are frequent. As with neutropenia, aphthous ulcers of mucous membranes, severe gingivitis, and periodontal disease are also major complications. In general, *S aureus* or gram-negative organisms are commonly isolated from infected sites; other organisms may be specifically associated with a defined neutrophil function defect. In some disorders, fungi account for an increasing number of infections. Deep or generalized infections, such as osteomyelitis, liver abscesses, pneumonitis, sepsis, meningitis, and necrotic or gangrenous soft-tissue lesions, occur in specific syndromes (eg, leukocyte adherence deficiency or chronic granulomatous disease). Patients with severe neutrophil dysfunction may die in childhood from severe infections and associated complications. Table 30–6 summarizes pertinent laboratory findings.

**Treatment**

The mainstay of management of these disorders is anticipation of infections and aggressive attempts to identify the foci and the causative agents. Surgical procedures to achieve these goals may be both diagnostic and therapeutic. Broad-spectrum antibiotics covering the range of possible organisms should be initiated without delay, switching to specific antimicrobial agents when the microbiologic diagnosis is made. When infections are unresponsive or they recur, granulocyte transfusions may be helpful.

Chronic management may include prophylactic antibiotics. Trimethoprim-sulfamethoxazole and some other antibiotics (eg, rifampin) enhance the bactericidal activity

of neutrophils from patients with chronic granulomatous disease. Some patients with Chédiak-Higashi syndrome improve clinically when given ascorbic acid. Recombinant γ-interferon decreases the number and severity of infections in patients with chronic granulomatous disease. Demonstration of this activity with one patient group raises the possibility that cytokines, growth factors, and other biologic response modifiers may be helpful in other conditions in preventing recurrent infections. Bone marrow transplant has been attempted in most major congenital neutrophil dysfunction syndromes, and reconstitution with normal cells and cell function has been documented. Combining genetic engineering with autologous bone marrow transplant may provide a future strategy for curing these disorders.

Prognosis

For mild to moderate defects, anticipation and conservative medical management ensure a better outlook. For severe defects, excessive morbidity and significant mortality still exist. In some diseases, the development of noninfectious complications, such as the lymphoproliferative phase of Chédiak-Higashi syndrome or inflammatory syndromes in chronic granulomatous disease, may influence prognosis.

Diaz R: Granulocyte transfusions for children with infection and neutropenia or granulocyte dysfunction. Pediatr Hematol Oncol 2014;31:425 [PMID: 24383443].

Eosinophilia in infants and children is an absolute eosinophil count greater than 300/μL. Marrow eosinophil production is stimulated by the cytokine IL-5. Allergies, particularly those associated with asthma and eczema, are the most common primary causes of eosinophilia in children. Eosinophilia also occurs in drug reactions, with tumors (Hodgkin and non-Hodgkin lymphomas and brain tumors), and with immunodeficiency and histiocytosis syndromes. Increased eosinophil counts are a prominent feature of many invasive parasitic infections. Gastrointestinal disorders such as chronic hepatitis, ulcerative colitis, Crohn disease, and milk precipitin disease may be associated with eosinophilia. Increased blood eosinophil counts have been identified in several families without association with any specific illness. Rare causes of eosinophilia include the hypereosinophilic syndrome, characterized by counts greater than 1500/μL and organ involvement and damage (hepatosplenomegaly, cardiomyopathy, pulmonary fibrosis, and central nervous system injury). This is a disorder of middle-aged adults and is rare in children. Eosinophilic leukemia has been described, but its existence as a distinct entity is very rare. Eosinophils are sometimes the last type of mature myeloid cell to disappear after marrow ablative chemotherapy. Increased eosinophil counts are associated with graft-versus-host disease after bone marrow transplant, and elevations are sometimes documented during rejection episodes in patients who have solid organ grafts.

BLEEDING DISORDERS

Bleeding disorders may occur as a result of (1) quantitative or qualitative abnormalities of platelets, (2) quantitative or qualitative abnormalities in plasma procoagulant factors, (3) vascular abnormalities, or (4) accelerated fibrinolysis. The coagulation cascade and fibrinolytic system are shown in Figures 30–4 and 30–5.
The most critical aspect in evaluating the bleeding patient is obtaining detailed personal and family bleeding histories, including bleeding complications associated with birth and the perinatal period, dental interventions, minor procedures, surgeries, and trauma. Excessive mucosal bleeding is suggestive of a platelet disorder, von Willebrand disease (vWD), dysfibrinogenemia, or vasculitis. Bleeding into muscles and joints may be associated with a plasma procoagulant factor abnormality. In either scenario, the abnormality may be congenital or acquired. A thorough physical examination should be performed with special attention to the skin, oral and nasopharynx, liver, spleen, and joints. Screening and diagnostic evaluation in patients with suspected bleeding disorders may include the following laboratory testing:

2. Activated partial thromboplastin time (aPTT) to assess clotting function of high-molecular-weight kininogen, prekallikrein, XII, XI, IX, VIII, X, V, II, and fibrinogen.
3. Platelet count and size determined as part of a CBC.
4. Platelet functional assessment by platelet function analyzer-100 (PFA-100), template bleeding time, or whole blood platelet aggregometry.
5. Fibrinogen functional level by clotting assay.

The following laboratory tests may also be useful:

1. Thrombin time to measure the generation of fibrin from fibrinogen following conversion of prothrombin to thrombin, as well as the antithrombin effects of fibrin-split products and heparin. The thrombin time may be prolonged in the setting of a normal fibrinogen concentration if the fibrinogen is dysfunctional (ie, dysfibrinogenemia).
2. Euglobulin lysis time (ELT) to evaluate for hyperfibrinolysis if the preceding workup is nonrevealing despite documented history of bleeding. If the ELT is shortened, assess hyperfibrinolysis due to a congenital deficiency of the fibrinolytic inhibitors plasminogen activator inhibitor-1 and α2-antiplasmin. In ill patients, measurement of fibrin degradation products may assist in the diagnosis of DIC.

ABNORMALITIES OF PLATELET NUMBER OR FUNCTION

Thrombocytopenia in the pediatric age range is often immune-mediated (e.g., ITP, neonatal auto- or alloimmune thrombocytopenia), but is also caused by consumptive coagulopathy (e.g., DIC, Kasabach-Merritt phenomenon), acute leukemias, or rarer disorders such as Wiskott-Aldrich syndrome and type 2b vWD, and artifactually in automated cytometers (e.g., Bernard-Soulier syndrome), where giant forms may not be enumerated as platelets.

1. Idiopathic Thrombocytopenic Purpura

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Otherwise healthy child.
- Decreased platelet count.
- Petechiae, ecchymoses.

**General Considerations**

Acute ITP is the most common bleeding disorder of childhood. It occurs most frequently in children aged 2–5 years and often follows infection with viruses, such as rubella, varicella, measles, parvovirus, influenza, EBV, or HIV. The thrombocytopenia results from clearance of circulating IgM- or IgG-coated platelets by the reticuloendothelial system. The spleen plays a predominant role in the disease by forming the platelet cross-reactive antibodies and sequestering the antibody-bound platelets. Most patients recover spontaneously within months. Chronic ITP (> 12 months duration) occurs in 10%–20% of affected patients.

**Clinical Findings**

A. **Symptoms and Signs**

Onset of ITP is usually acute, with the appearance of multiple petechiae and ecchymoses. Epistaxis is common at presentation. No other physical findings are usually present. Rarely, concurrent infection with EBV or CMV may cause hepatosplenomegaly or lymphadenopathy, simulating acute leukemia.

B. **Laboratory Findings**

1. **Blood**—The platelet count is markedly reduced (usually < 50,000/μL and often < 10,000/μL), and large platelets are present in the peripheral blood smear, suggesting accelerated new platelet production. The white blood count and differential are normal, and the hemoglobin concentration is preserved unless hemorrhage has been significant.

2. **Bone marrow**—Megakaryocyte hyperplasia with normal erythroid and myeloid cellularity.

3. **Other laboratory tests**—Platelet-associated IgG or IgM, or both, may be demonstrated on the platelets or in the serum. PT and aPTT are normal.

**Differential Diagnosis**

Table 30–7 lists common causes of thrombocytopenia. ITP remains a diagnosis of exclusion. Family history or the finding of predominantly giant platelets on the peripheral blood smear is helpful in distinguishing from hereditary thrombocytopenia. Bone marrow examination should be performed if the history is atypical (i.e., the child is not otherwise healthy, or there is a family history of bleeding), if abnormalities other than purpura and petechiae are present on physical examination, or if other cell lines are abnormal on the CBC. Bone marrow examination prior to treatment with corticosteroids remains controversial.

Complications
Severe hemorrhage and bleeding into vital organs are feared complications of ITP. Intracranial hemorrhage is the most serious complication, occurring in less than 1% of affected children. The most important risk factors for hemorrhage are a platelet count less than 10,000/µL and mean platelet volume less than 8 fl.

Treatment
A. General Measures
Observation is recommended for most children in the absence of bleeding regardless of platelet count. Aspirin, other medications (eg, NSAIDs such as Advil, Naproxin, etc) that compromise platelet function should be avoided. Bleeding precautions (eg, restriction from physical contact activities and use of helmets) should be observed. Platelet transfusion should be avoided except in circumstances of life-threatening bleeding, in which case emergent splenectomy may be considered. In this setting, administration of corticosteroids and IVIG is also advisable.

B. Corticosteroids
Patients with clinically significant, but non–life-threatening bleeding (ie, epistaxis, hematuria, and hematochezia) and those with a platelet count of less than 10,000/dL may benefit from treatment with corticosteroids. No single dose or dosing regimen has evidence to support its use above another. Prednisone 2 mg/kg/day (maximum of 60 mg/day) for 14–21 days, or alternatively, prednisone 4 mg/kg/day for 7 days, with a taper to day 14–21 are commonly used regimens. An initial higher dose (3–5 mg/kg/day) for 3–7 days may lead to faster count recovery. Long-term use of corticosteroids should be avoided because of toxicity.

C. Intravenous Immunoglobulin
Intravenous immunoglobulin (IVIG) is the treatment of choice for severe, acute bleeding, and may also be used as an alternative or adjunct to corticosteroid treatment in both acute and chronic ITP. IVIG may be effective when the patient is resistant to corticosteroids; responses are prompt and may last for several weeks. A single dose of 0.8–1 g/kg has been recommended. Platelets may be given simultaneously during life-threatening hemorrhage but are rapidly destroyed. Side effects of IVIG are common, including transient neurologic complications in one-third of patients (eg, headache, nausea, and aseptic meningitis) that mimic intracranial hemorrhage and necessitate radiologic evaluation. A transient decrease in neutrophil number may also be seen, and hemolytic anemia is rare.

D. Anti-Rh(D) Immunoglobulin
This polyclonal immunoglobulin binds to the D antigen on RBCs. The splenic clearance of anti-D–coated red cells interferes with removal of antibody-coated platelets, resulting in improvement in platelet count. This approach is effective only in Rh(+) patients with a functional spleen who are DAT negative. At doses of 50–75 mcg/kg, approximately 80% of Rh+ children with acute or chronic ITP respond; however, there is no clear difference between Anti-D and IVIG in the time to reach a platelet count of 20 × 10⁹/L. Significant hemolysis may occur in up to 5% of patients. The FDA has provided specific monitoring requirements because of reports of fatal intravascular hemolysis.

E. Splenectomy
Many children with chronic ITP have platelet counts less than 30,000/µL. Up to 70% of such children recover with a platelet count less than 100,000/µL within 1 year. For the remainder, corticosteroids, IVIG, and anti-D immunoglobulin are typically effective treatment for acute bleeding. Splenectomy produces a complete response in 70% and partial response in 20% of children with ITP, but should be considered only after persistence of significant thrombocytopenia for more than 12 months, and the failure of a preferred or alternative second-line therapy. The risk of overwhelming infection with encapsulated organisms is increased after splenectomy, particularly in the young child. Preoperative vaccination with polyvalent pneumococcal conjugate and polysaccharide vaccines, meningococcal C conjugate, and H. influenza b conjugate is recommended. If possible, the splenectomy should be postponed, until age 5 years. For patients younger than 5 years, daily penicillin prophylaxis should be started postoperatively and continued at least until 5 years of age. Postoperatively, a reactive thrombocytosis may raise the platelet count to more than 1 million/µL, but is not associated with thrombotic complications in children. However, thrombosis is recognized as a potential post-splenectomy complication in the long term.

F. Rituximab (Anti-CD20 Monoclonal Antibody)
There have been no randomized trials for rituximab in children. The efficacy of treating childhood chronic ITP in several series and case studies has demonstrated response rates between 26% and 60%. Because of significant adverse events, this therapy may be reserved for refractory cases with significant bleeding or as an alternative to splenectomy.

G. New Agents
Thrombopoietin receptor agonists are now available for the treatment of ITP for children. One randomized clinical
trial in children with romiplostim, showed an 88% response rate and improved quality of life. In addition, as a second-line agent, they may be useful in patients for corticosteroid sparing. One pitfall of this approach is that these agents require long-term administration, and continued study in children are addressing long-term adverse effects, efficacy, and sustained response.

**Prognosis**

Eighty percent of children with ITP will achieve a remission. Predictors of the development of chronic ITP include female gender, age greater than 10 years at presentation, insidious onset of bruising, and the presence of other autoantibodies. Older child- and adolescent-onset ITP is associated with an increased incidence of chronic autoimmune diseases or immunodeficiency states. Appropriate screening by history and laboratory studies is warranted.

2. Thrombocytopenia in the Newborn

Thrombocytopenia is one of the most common causes of neonatal hemorrhage and should be considered in any newborn with petechiae, purpura, or other significant bleeding. Defined by a platelet count of less than 150,000/μL, thrombocytopenia occurs in approximately 0.9% of unselected neonates; however, up to 80% of neonates in a newborn intensive care unit may experience thrombocytopenia; most of these cases are transient. Several specific entities may be responsible for more severe thrombocytopenia (see Table 30–7). Infection and DIC are the most common causes of thrombocytopenia in ill-term newborns and in preterm newborns. In the healthy neonate, antibody-mediated thrombocytopenia (alloimmune or maternal autoimmune), viral syndromes, hyperviscosity, and major-vessel thrombosis are frequent causes of thrombocytopenia. Management is directed toward the underlying etiology. Other infants are affected by unknown mechanisms in mothers with preeclampsia. Most of these cases resolve over several days to a few weeks without treatment, but some are severe enough to warrant platelet transfusions.

A. Thrombocytopenia Associated With Platelet Alloantibodies (Neonatal Alloimmune Thrombocytopenia-NAIT)

NAIT is the most common cause of thrombocytopenia in well, term infants, with a prevalence of 0.7 per 1000 pregnancies. Alloimmunization occurs when a platelet antigen of the infant differs from that of the mother, and the mother is sensitized by fetal platelets that cross the placenta into the maternal circulation. In Caucasians, 80% are associated with HPA1a, and 10%-15% HPA5b. Sensitization of a mother homozygous for HPA-1b to paternally acquired fetal HPA-1a antigen results in severe fetal thrombocytopenia in 1 in 1200 fetuses. Only 1 in 20 HPA-1a–positive fetuses of HPA-1a–negative mothers develop alloimmunization. Other platelet-specific alloantigens may be etiologic. Unlike in Rh incompatibility, 30%-40% of affected neonates are first-born. Thrombocytopenia is progressive over the course of gestation and worse with each subsequent pregnancy. The presence of antenatal maternal platelet antibodies on more than one occasion and their persistence into the third trimester is predictive of severe neonatal thrombocytopenia; a weak or undetectable antibody does not exclude thrombocytopenia. Severe intracranial hemorrhage occurs in 10%-30% of affected neonates as early as 20 weeks gestation. Petechiae or other bleeding manifestations are usually present shortly after birth. The disease is self-limited, and the platelet count normalizes within 4 weeks.

If alloimmunization is associated with clinically significant bleeding, transfusion of platelets harvested from the mother is more effective than random donor platelets in increasing the platelet count. Transfusion with HPA-matched platelets from unrelated donors or treatment with IVIG or methylprednisolone to acutely block macrophage uptake of sensitized platelets has also been successful in raising the platelet count and achieving hemostasis. If thrombocytopenia is not severe and bleeding is absent, observation alone is often appropriate.

Intracranial hemorrhage in a previous child secondary to alloimmune thrombocytopenia is the strongest risk factor for severe fetal thrombocytopenia and hemorrhage in a subsequent pregnancy. Amniocentesis or chorionic villus sampling to obtain fetal DNA for platelet antigen typing is sometimes performed if the father is heterozygous for HPA-1a. If alloimmunization has occurred with a previous pregnancy, irrespective of history of intracranial hemorrhage, screening cranial ultrasound for hemorrhage should begin at 20 weeks gestation and be repeated regularly. In addition, cordocentesis should be performed at approximately 20 weeks gestation, with prophylactic transfusion of irradiated, leukoreduced, maternal platelet concentrates. If the fetal platelet count is less than 100,000/μL, the mother should be treated with weekly IVIG. Delivery by elective cesarean section is recommended if the fetal platelet count
is less than 50,000/μL to minimize the risk of intracranial hemorrhage associated with birth trauma.

**B. Thrombocytopenia Associated With ITP in the Mother (Neonatal Autoimmune Thrombocytopenia)**

Infants born to mothers with ITP or other autoimmune diseases (eg, antiphospholipid antibody syndrome or systemic lupus erythematosus) may develop thrombocytopenia as a result of transfer of antiplatelet IgG from the mother to the infant. Unfortunately, maternal and fetal platelet counts and maternal antiplatelet antibody levels are unreliable predictors of bleeding risk. Antenatal corticosteroid administration to the mother is generally instituted once maternal platelet count falls below 50,000/μL, with or without a concomitant course of IVIG.

Most neonates with autoimmune thrombocytopenia do not develop clinically significant bleeding, and treatment is not often required. The risk of intracranial hemorrhage is 0.2%–2%. If diffuse petechiae or minor bleeding are evident, a 1- to 2-week course of oral prednisone, 2 mg/kg/day, may be helpful. If the platelet count remains consistently less than 20,000/μL or if severe hemorrhage develops, IVIG should be given (0.8–1 g/kg daily for 1–2 days). Platelet transfusions are only indicated for life-threatening bleeding, and may only be effective after removal of antibody by exchange transfusion. The platelet nadir is typically between the fourth and sixth day of life and improves significantly by 1 month; full recovery may take 2–4 months. Platelet recovery may be delayed in breast-fed infants because of transfer of IgG to the milk.

**C. Neonatal Thrombocytopenia Associated With Infections**

Thrombocytopenia is commonly associated with severe generalized infections during the newborn period. Between 50% and 75% of neonates with bacterial sepsis are thrombocytopenic. Intrauterine infections such as rubella, syphilis, toxoplasmosis, HIV, CMV, herpes simplex (acquired intra- or postpartum), enteroviruses, and parvovirus are often associated with thrombocytopenia. In addition to specific treatment for the underlying disease, platelet transfusions may be indicated in severe cases.

**D. Thrombocytopenia Associated With Kaposiform Hemangioendotheliomas (Kasabach-Merritt Syndrome)**

A rare but important cause of thrombocytopenia in the newborn is kaposiform hemangioendothelioma, a benign neoplasm with histopathology distinct from that of classic infantile hemangiomas. Intense platelet sequestration in the lesion results in thrombocytopenia and may rarely be associated with a DIC-like picture and hemolytic anemia.

The bone marrow typically shows megakaryocytic hyperplasia in response to the thrombocytopenia. Corticosteroids, α-interferon, vincristine, and sirolimus are all useful for reducing the size of the lesion and are indicated if significant coagulopathy is present, the lesion compresses a vital structure, or the lesion is cosmetically unacceptable. If consumptive coagulopathy is present, heparin or an antifibrinolytic agent may be useful. Depending on the site, embolization may be an option. Surgery is often avoided because of the high risk of hemorrhage.

**3. Disorders of Platelet Function**

Individuals with platelet function defects typically develop abnormal bruising and mucosal bleeding similar to that occurring in persons with thrombocytopenia. The PFA-100, which can evaluate platelet dysfunction and vWD, has replaced the template bleeding time in many institutions but is not unanimously endorsed. Although labor-intensive, platelet aggregometry remains important in selected clinical situations. Platelet aggregometry is now used for in vitro assessment of platelet function, and uses agonists, such as adenosine diphosphate, collagen, arachidonic acid, and ristocetin. Unfortunately, none of these screening tests of platelet function uniformly predicts clinical bleeding severity.

Platelet dysfunction may be inherited or acquired, with the latter being more common. Acquired disorders of platelet function may occur secondary to uremia, cirrhosis, sepsis, myeloproliferative disorders, congenital heart disease, and viral infections. Many pharmacologic agents decrease platelet function. The most common offending agents in the pediatric population are aspirin and other NSAIDs, synthetic penicillins, and valproic acid. In acquired platelet dysfunction, the PFA-100 closure time is prolonged with collagen-epinephrine, while normal with collagen-ADP.

The inherited disorders are due to defects in platelet-vessel interaction, platelet-platelet interaction, platelet granule content or release (including defects of signal transduction), thromboxane and arachidonic acid pathway, and platelet-procoagulant protein interaction. Individuals with hereditary platelet dysfunction have a prolonged bleeding time with normal platelet number and morphology by light microscopy. PFA-100 closure time is typically prolonged with both collagen-ADP and collagen-epinephrine.

Congenital causes of defective platelet-vessel wall interaction include Bernard-Soulier syndrome, which is characterized by increased platelet size and decreased
platelet number. The molecular defect in this autosomal recessive disorder is a deficiency or dysfunction of glycoprotein Ib-V-IX complex on the platelet surface resulting in impaired von Willebrand factor (vWF) binding, and hence, impaired platelet adhesion to the vascular endothelium.

Glanzmann thrombasthenia is an example of severe platelet-platelet dysfunction. In this autosomal recessive disorder, glycoprotein IIb-IIIa is deficient or dysfunctional. Platelets do not bind fibrinogen effectively and exhibit impaired aggregation. As in Bernard-Soulier syndrome, acute bleeding is treated by platelet transfusion, and more recently with recombinant factor VIIa.

Disorders involving platelet granule content include storage pool disease and Quebec platelet disorder. In individuals with storage pool disease, platelet-dense granules lack adenosine dinucleotide phosphate and adenosine trinucleotide phosphate and are found to be low in number by electron microscopy. These granules are also deficient in Hermansky-Pudlak, Chédiak-Higashi, and Wiskott-Aldrich syndromes. Whereas deficiency of a second granule class, α-granules, results in the gray platelet syndrome, Quebec platelet disorder is characterized by a normal platelet α-granule number, but with abnormal proteolysis of α-granule proteins and deficiency of platelet α-granule multimerin. α-Granule abnormality in this disorder also results in increased serum levels of urokinase-type plasminogen activator. Epinephrine-induced platelet aggregation is markedly impaired.

Platelet dysfunction has also been observed in other congenital syndromes, such as Down and Noonan syndromes, without a clear understanding of the molecular defect.

### Treatment

Acute bleeding in many individuals with acquired or selected congenital platelet function defects responds to therapy with desmopressin acetate, likely due to an induced release of vWF from endothelial stores and/or upregulated expression of glycoprotein Ib-V-IX on the platelet surface. If this therapy is ineffective, or if the patient has Bernard-Soulier syndrome or Glanzmann syndrome, the mainstay of treatment for bleeding episodes is platelet transfusion, possibly with HLA type-specific platelets. Recombinant VIIa, which has variable efficacy and may be helpful in platelet transfusion-refractory patients, is FDA-approved for patients with Glanzmann syndrome.

### ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Bruising, soft-tissue bleeding, hemarthrosis.
- Prolonged aPTT.
- Reduced factor VIII activity.

### General Considerations

Factor VIII activity is reported in units per milliliter, with 1 U/mL equal to 100% of the factor activity found in 1 mL of normal plasma. The normal range for factor VIII activity is 0.50–1.50 U/mL (50%–150%). Hemophilia A occurs predominantly in males as an X-linked disorder. One-third of cases are due to a spontaneous mutation. The incidence of factor VIII deficiency is 1:5000 male births.

### Clinical Findings

#### A. Symptoms and Signs

Persons with hemophilia who have less than 1% factor VIII activity have severe hemophilia A, and have frequent spontaneous bleeding episodes involving skin, mucous membranes, joints, muscles, and viscera. In contrast, patients with mild hemophilia A (5%–40% factor VIII activity) mainly bleed at times of trauma or surgery. Those with moderate hemophilia A (1% to <5% factor VIII activity) typically have intermediate bleeding manifestations. The most crippling aspect of factor VIII deficiency is the tendency to develop recurrent hemarthroses that incite joint destruction.

#### B. Laboratory Findings

Individuals with hemophilia A have a prolonged aPTT, except in some cases of mild deficiency. The PT is normal. The diagnosis is confirmed by finding decreased factor VIII activity with normal vWF activity. In two-thirds of families of hemophilic patients, the females are carriers and some manifest symptomatic bleeding. Carriers of hemophilia can be diagnosed by DNA sequencing, and their bleeding severity by factor activity. In a male fetus or newborn with a family history of hemophilia A, cord blood sampling for factor VIII activity is accurate and important for subsequent care.

New York: McGraw-Hill; 2001.
Complications

Intracranial hemorrhage is the leading disease-related cause of death among persons with hemophilia. Most intracranial hemorrhages in moderate to severe deficiency are spontaneous and not associated with trauma. Hemarthroses begin early in childhood and, particularly when recurrent, can result in joint destruction (ie, hemophilic arthropathy). Large intramuscular hematomas can lead to a compartment syndrome with resultant neurologic compromise, or pseudotumors. Although these complications are most common in severe hemophilia A, they may be experienced by individuals with moderate or mild disease. Acquired neutralizing antibodies to factor VIII is a potential serious complication after treatment with factor VIII concentrate. These antibodies develop in up to 30% of patients with severe hemophilia A, and especially in patients with large deletions in the factor VIII gene. Inhibitors may be amenable to desensitization with regular factor VIII infusion (immune tolerance therapy). Bypassing agent therapy with recombinant factor VIIa and/or FEIBA has become standard treatment of acute hemorrhage in patients with hemophilia A and a high-titer inhibitor, and may also be used for prophylaxis.

In prior decades, therapy-related complications in hemophilia A have included factor-related infection with HIV, hepatitis B virus, and hepatitis C virus. Through stringent donor selection, the implementation of sensitive screening assays, the use of heat or chemical methods for viral inactivation, and the development of recombinant products, the risk of these infections is effectively eliminated. Inactivation methods do not eradicate viruses lacking a lipid envelope; however, so that transmission of parvovirus and hepatitis A remains a concern with the use of plasma-derived products. Immunization with hepatitis A and hepatitis B vaccines is recommended for all hemophilia patients.

Treatment

The general aim of management is to raise the factor VIII activity to prevent or stop bleeding. Some patients with mild factor VIII deficiency may respond to desmopressin via release of endothelial stores of factor VIII and vWF into plasma; however, most patients require administration of exogenous factor VIII to achieve hemostasis. The in vivo half-life of infused factor VIII is 6–14 hours but varies among individuals. Non–life-threatening, non–limb-threatening hemorrhage is treated with 20–30 U/kg of factor VIII, to achieve a rise in plasma factor VIII activity to 40%–60%. Joint hemarthrosis and life- or limb-threatening hemorrhage is treated with 50 U/kg of factor VIII, targeting a rise to 100% factor VIII activity. Subsequent doses are determined according to the site and extent of bleeding, and clinical response to FVIII infusion. In circumstances of poor clinical response, recent change in bleeding frequency, or comorbid illness, monitoring the plasma factor VIII activity response is recommended. For most instances of non–life-threatening hemorrhage in experienced patients with moderate or severe hemophilia A, treatment can be administered at home, provided adequate intravenous access and management with the hemophilia treatment center.

Prophylactic factor VIII infusions prevent the development of arthropathy in severe and moderate hemophilia, and is the standard of care in pediatric hemophilia. Extended half-life factor VIII concentrates have been approved by the FDA with the hope of decreasing infusions and improving clinical outcomes. In addition, multiple non-factor replacement strategies (eg, emicizumab, fitusiran, concizumab) are emerging that may replace factor VIII for prophylaxis and are disruptive technologies. Along with gene therapy, they look to reshape the lives and outcomes of PWH.

Prognosis

The development of innovative, safe and, effective therapies for hemophilia A has resulted in improved long-term survival in recent decades. In addition, comprehensive care managed through hemophilia treatment centers have greatly improved quality of life and level of function.

2. Factor IX Deficiency (Hemophilia B, Christmas Disease)

The mode of inheritance and clinical manifestations of factor IX deficiency are the same as those of factor VIII deficiency. Hemophilia B is 15%–20% as prevalent as hemophilia A. Factor IX deficiency is associated with a prolonged aPTT, but normal PT and thrombin time. However, the aPTT is slightly less sensitive to factor IX deficiency than factor VIII deficiency. Diagnosis of hemophilia B is made by assaying factor IX activity, and severity is determined similar to hemophilia A.

The mainstay of treatment in hemophilia B is exogenous factor IX. Unlike factor VIII, about 50% of the administered dose of factor IX diffuses into the extravascular space. Therefore, 1 U/kg of plasma-derived factor IX concentrate or recombinant factor IX is expected to increase plasma factor IX activity by approximately 1%. Factor IX typically has a half-life of 18–22 hours in vivo. In contrast to severe factor VIII deficiency, only 1%–3% of persons with factor IX deficiency develop a factor IX inhibitor, but patients may be at risk for anaphylaxis when receiving exogenous factor IX. The prognosis for persons with factor IX deficiency is comparable to that of patients with factor VIII deficiency. Extended half-life factor concentrates have changed treatment of severe and moderate hemophilia B. Gene therapy and non-factor replacement technologies are in clinical trial.
HEMATOLOGIC DISORDERS

3. Factor XI Deficiency (Hemophilia C)

Factor XI deficiency is a genetic, autosomally transmitted coagulopathy, typically of mild to moderate clinical severity. Cases of factor XI deficiency account for less than 5% of all persons living with hemophilia. Homozygotes generally bleed at surgery or following severe trauma and at hyperfibrinolytic sites, but do not commonly have spontaneous hemarthroses. In contrast to factor VIII and IX deficiencies, factor XI activity is least predictive of bleeding risk. Pathologic bleeding may be seen in heterozygous individuals with factor XI activity as high as 60%. The aPTT is often considerably prolonged. In individuals with deficiency of both plasma and platelet-associated factor XI, the PFA-100 may also be prolonged. Management typically consists of perioperative prophylaxis and episodic therapy for acute hemorrhage. Treatment includes infusion of fresh frozen plasma (FFP); platelet transfusion may also be useful for acute hemorrhage in patients with deficiency of platelet-associated factor XI. Desmopressin has been used in some cases, and antifibrinolytic therapy is common. The prognosis for an average life span in patients with factor XI deficiency is excellent.

4. Other Inherited Bleeding Disorders

Other hereditary single clotting factor deficiencies are rare. Transmission is generally autosomal. Homozygous individuals with a deficiency or structural abnormality of prothrombin, factor V, factor VII, or factor X may have excessive bleeding.

Persons with dysfibrinogenemia (ie, structurally or functionally abnormal fibrinogen) may develop recurrent venous thromboembolic episodes or bleeding. Immunologic assay of fibrinogen is normal, but clotting assay may be low and the thrombin time prolonged. The PT and aPTT may be prolonged. Fibrinogen concentrates are now widely available.

Afibrinogenemia resembles hemophilia clinically but has an autosomal recessive inheritance. Affected patients can experience a variety of bleeding manifestations, including mucosal bleeding, ecchymoses, hematomas, hemarthroses, and intracranial hemorrhage, especially following trauma. Fatal umbilical cord hemorrhage has been reported in neonates. The PT, aPTT, and thrombin time are all prolonged. A severely reduced fibrinogen concentration in an otherwise well child is confirmatory of the diagnosis.

As in dysfibrinogenemia, fibrinogen concentrates are used for surgical prophylaxis and for acute hemorrhage.

James P: Rare bleeding disorders—bleeding assessment tools, laboratory aspects and phenotype and therapy of FXI deficiency. Haemophilia 2014 May;20 Suppl 4:71–75 [PMID: 24762279].

VON WILLEBRAND DISEASE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Easy bruising and epistaxis from early childhood.
- Menorrhagia.
- Prolonged PFA-100 (or bleeding time), normal platelet count, absence of acquired platelet dysfunction.
- Reduced amount or abnormal activity of von Williebrand factor (vWF).

General Considerations

von Willebrand disease (vWD) is the most common inherited bleeding disorder among Caucasians, with a prevalence as high as 1%. vWF is a multimeric plasma protein that binds factor VIII and is a cofactor for platelet adhesion to the endothelium. An estimated 70%–80% of all patients with vWD have classic vWD (type 1), caused by a partial quantitative deficiency of vWF. vWD type 2 involves a qualitative deficiency of (ie, dysfunctional) vWF, and vWD type 3 is characterized by a nearly complete deficiency of vWF. vWD is most often transmitted as an autosomal dominant trait, but it can be autosomal recessive. The disease can also be acquired, developing in association with hypothyroidism, Wilms tumor, cardiac disease, renal disease, or systemic lupus erythematosus, and in individuals receiving valproic acid. Acquired vWD is most often caused by the development of an antibody to vWF or increased turnover of vWF.

Clinical Findings

A. Symptoms and Signs

A history of increased bruising and excessive epistaxis is often present. Prolonged bleeding also occurs with trauma or at surgery. Menorrhagia is often a presenting finding in females.

B. Laboratory Findings

PT is normal, and aPTT is prolonged if factor VIII is decreased. Prolongation of the PFA-100 or bleeding time is
usually present since vWF plays a role in platelet adherence to endothelium. Platelet number may be decreased in type 2b vWD. Factor VIII and vWF antigen are decreased in types 1 and 3, but may be normal in type 2 vWD. vWF activity (eg, ristocetin cofactor or collagen binding) is decreased in all types. Since normal vWF antigen levels vary by blood type (type O normally has lower levels), blood type must be determined. Complete laboratory classification also requires vWF multimer assay. The diagnosis requires confirmatory laboratory testing.

**Treatment**

Desmopressin acetate can be given intravenously or subcutaneously to prevent or halt bleeding for many patients with vWD types 1 and 2, by releasing vWF from endothelial stores. In responding patients, the increase in vWF and factor VIII in the plasma can be two- to fivefold. A high-concentration desmopressin nasal spray (150 mcg/spray), different from the preparation used for enuresis, may also be used. Because response to vWF is variable among patients, factor VIII and vWF activities are typically measured before, 30–60 minutes post, and 4 hours after desmopressin administration to document response. Desmopressin causes fluid retention which can result in hyponatremia; therefore, fluid restriction should be discussed, especially in children younger than 2 years. Because release of stored vWF is limited, tachyphylaxis often occurs after 2–3 administered doses of desmopressin.

If further therapy is indicated, vWF-replacement therapy (plasma derived or recombinant VWF) is recommended; such therapy is also used in patients with type 1 or 2a vWD who exhibit suboptimal laboratory response to desmopressin, and for all individuals with type 2b or 3 vWD. Antifibrinolytic agents (eg, e-aminocaproic acid and tranexamic acid) are useful for control of mucosal bleeding. Estrogen-containing contraceptive therapy may be helpful for menorrhagia as they may limit menstrual bleeding and increase vWF levels.

**Prognosis**

With the availability of effective treatment and prophylaxis for bleeding, life expectancy in vWD is normal.

**ACQUIRED BLEEDING DISORDERS**

1. **Disseminated Intravascular Coagulation**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Presence of a disorder known to trigger DIC.
- Evidence for consumptive coagulopathy (prolonged aPTT, PT, or thrombin time; increase in FSPs [fibrin-fibrinogen split products]; decreased FSPs or platelets).

**General Considerations**

Disseminated intravascular coagulation (DIC) is an acquired pathologic process characterized by tissue factor–mediated coagulation activation in the host. DIC involves dysregulated, excessive thrombin generation, with consequent intravascular fibrin deposition and consumption of platelets and procoagulant factors. Microthrombi, composed of fibrin and platelets, may produce tissue ischemia and end-organ damage. The fibrinolytic system is frequently activated in DIC, leading to plasmin-mediated destruction of fibrin and fibrinogen; this results in fibrin-fibrinogen degradation products (FDPs) which exhibit anticoagulant and platelet-inhibitory functions. DIC commonly accompanies severe infection and other critical illnesses in infants and children. Conditions known to trigger DIC include endothelial damage (eg, endotoxin, virus), tissue necrosis (eg, burns), diffuse ischemic injury (eg, shock, hypoxia acidosis), and systemic release of tissue procoagulants (eg, certain cancers, placental disorders).

**Clinical Findings**

**A. Symptoms and Signs**

Signs of DIC may include (1) complications of shock, often including end-organ dysfunction, (2) diffuse bleeding tendency (eg, hematuria, melena, purpura, petechiae, persistent oozing from needle punctures or other invasive procedures), and (3) evidence of thrombotic lesions (eg, small and major vessel thrombosis, purpura fulminans).

**B. Laboratory Findings**

Tests that are sensitive, easiest to perform, useful for monitoring, and reflect the hemostatic capacity of the patient are the PT, aPTT, platelet count, fibrinogen, and FDPs (including D-dimer). The PT and aPTT are typically prolonged and the platelet count and fibrinogen concentration...
may be decreased. However, in children, the fibrinogen level may be normal until late in the course. Levels of FSPs are increased, and elevated levels of D-dimer, a cross-linked fibrin degradation byproduct, may be helpful in monitoring the degree of activation of both coagulation and fibrinolysis. However, D-dimer is nonspecific and may be elevated in the context of a triggering event (eg, severe infection) without concomitant DIC. Often, physiologic inhibitors of coagulation, especially antithrombin III, protein C, and protein S are consumed, predisposing to thrombosis. The specific laboratory abnormalities in DIC may vary with the triggering event and the course of illness.

**Differential Diagnosis**

DIC can be difficult to distinguish from coagulopathy of liver disease (ie, hepatic synthetic dysfunction), especially when the latter is associated with thrombocytopenia secondary to portal hypertension and hypersplenism. Generally, factor VII activity is decreased markedly in liver disease (due to deficient synthesis of this protein, which has the shortest half-life among the procoagulant factors), but only mildly to moderately decreased in DIC (due to consumption). Factor VIII activity is often normal or even increased in liver disease, but decreased in DIC.

**Treatment**

**A. Therapy for Underlying Disorder**

The most important aspect of therapy in DIC is the identification and treatment of the triggering event. If the pathogenic process underlying DIC is reversed, often no other therapy is needed for the coagulopathy.

**B. Replacement Therapy for Consumptive Coagulopathy**

Replacement of consumed procoagulant factors with FFP, cryoprecipitate, unactivated prothrombin complex concentrates (PCCs), and platelets is warranted in the setting of DIC with hemorrhagic complications, or as periprocedural bleeding prophylaxis. Infusion of 10–15 mL/kg FFP typically raises procoagulant factor activities by approximately 10%–15%. Cryoprecipitate can also be given as a rich source of fibrinogen; one bag of cryoprecipitate per 3 kg in infants or one bag of cryoprecipitate per 6 kg in older children typically raises plasma fibrinogen concentration by 75–100 mg/dL.

**C. Anticoagulant Therapy for Coagulation Activation**

Continuous intravenous infusion of unfractionated heparin is sometimes given in order to attenuate coagulation activation and consequent consumptive coagulopathy. The rationale for heparin therapy is to maximize the efficacy of, and minimize the need for, replacement of procoagulants and platelets; however, clinical evidence demonstrating benefit of heparin in DIC is lacking. Prophylactic doses of unfractionated heparin or low-molecular-weight heparin (LMWH) in critically ill and nonbleeding patients with DIC may be considered for prevention of venous thromboembolism. Unfractionated heparin dosing and monitoring is listed on page 946.

**D. Specific Factor Concentrates**

A nonrandomized pilot study of antithrombin concentrate in children with DIC and associated acquired antithrombin deficiency demonstrated favorable outcomes, suggesting that replacement of this consumed procoagulant may be beneficial. Protein C concentrate has also shown promise in two small pilot studies of meningococci-associated DIC with purpura fulminans. The potential of Activated protein C needs more study.

**2. Liver Disease**

The liver is the major synthetic site of prothrombin, fibrinogen, high-molecular-weight kininogen, and factors V, VII, IX, X, XI, XII, and XIII. Plasminogen and the physiologic anticoagulants (antithrombin III, protein C, and protein S) are synthesized in the liver, as is α₂-antiplasmin, a regulator of fibrinolysis. Deficiency of factor V and the vitamin K–dependent factors (II, VII, IX, and X) is most often a result of decreased hepatic synthesis, and is manifested by a prolonged PT and often a prolonged aPTT. Extravascular loss and increased consumption of clotting factors may contribute to PT and aPTT prolongation. Fibrinogen production is often decreased, or an abnormal fibrinogen (dysfibrinogen) containing excess sialic acid residues may be synthesized, or both. Hypofibrinogenemia or dysfibrinogenemia is associated with prolongation of thrombin time and reptilase time. FSPs and D-dimers may be present because of increased fibrinolysis, particularly in the setting of chronic hepatitis or cirrhosis. Thrombocytopenia secondary to hypersplenism may occur. DIC and the coagulopathy of liver disease also mimic vitamin K deficiency; however, vitamin K deficiency has normal factor V activity. Treatment of acute bleeding in the setting of coagulopathy of liver disease consists of replacement with FFP or PCCs and platelets. Desmopressin may shorten the bleeding time and aPTT in patients with chronic liver disease, but its safety is not well established. Recombinant VIIa also is efficacious for life-threatening refractory hemorrhage.

**3. Vitamin K Deficiency**

The newborn period is characterized by physiologically depressed activity of the vitamin K–dependent factors
(II, VII, IX, and X). If vitamin K is not administered at birth, a bleeding diathesis previously called hemorrhagic disease of the newborn, now termed vitamin K deficiency bleeding (VKDB), may develop. Outside of the newborn period, vitamin K deficiency may occur as a consequence of inadequate intake, excess loss, inadequate formation of active metabolites, or competitive antagonism.

One of three patterns is seen in the neonatal period:

1. Early VKDB of the newborn occurs within 24 hours of birth, most often manifested by cephalohematoma, intracranial hemorrhage, or intra-abdominal bleeding. Although occasionally idiopathic, it is most often associated with maternal ingestion of drugs that interfere with vitamin K metabolism (eg, warfarin, phenytoin, isoniazid, and rifampin). Early VKDB occurs in 6%-12% of neonates born to mothers who take these medications without receiving vitamin K supplementation. The disorder is often life threatening.

2. Classic VKDB occurs at 24 hours to 7 days of age and usually is manifested as gastrointestinal, skin, or mucosal bleeding. Bleeding after circumcision may occur. Although occasionally associated with maternal drug usage, it most often occurs in well infants who do not receive vitamin K at birth and are solely breast-fed.

3. Late neonatal VKDB occurs on or after day 8. Manifestations include intracranial, gastrointestinal, or skin bleeding. This disorder is often associated with fat malabsorption (eg, in chronic diarrhea) or alterations in intestinal flora (eg, with prolonged antibiotic therapy). Like classic VKDB, late VKDB occurs almost exclusively in breast-fed infants.

The diagnosis of vitamin K deficiency is suspected based on the history, physical examination, and laboratory results. The PT is prolonged out of proportion to the aPTT (also prolonged). The thrombin time becomes prolonged late in the course. The platelet count is normal. This laboratory profile is similar to the coagulopathy of acute liver disease, but with normal fibrinogen level and absence of hepatic transaminase elevation. The diagnosis of vitamin K deficiency is confirmed by a demonstration of non-carboxylation of specific clotting factors in the absence of vitamin K in the plasma and by clinical and laboratory responses to vitamin K. Intravenous or subcutaneous treatment with vitamin K should be given immediately and not withheld while awaiting test results. In the setting of severe bleeding, additional acute treatment with FFP or PCCs may be indicated.

4. Uremia

Uremia is frequently associated with acquired platelet dysfunction. Bleeding occurs in approximately 50% of patients with chronic renal failure. The bleeding risk conferred by platelet dysfunction associated with metabolic imbalance may be compounded by decreased vWF activity and procoagulant deficiencies (eg, factor II, XII, XI, and IX) due to increased urinary losses of these proteins in some settings of renal insufficiency. In accordance with platelet dysfunction, uremic bleeding is typically characterized by purpura, epistaxis, menorrhagia, or gastrointestinal hemorrhage. Acute bleeding may be managed with infusion of desmopressin acetate, factor VIII concentrates containing vWF, or cryoprecipitate with or without coadministration of FFP. Red cell transfusion may be required. Prophylactic administration of erythropoietin before the development of severe anemia which increases the potential for bleeding. Recombinant VIIa may be useful in refractory bleeding.

VASCULAR ABNORMALITIES ASSOCIATED WITH BLEEDING

1. Henoch-Schönlein Purpura (Anaphylactoid Purpura)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Purpuric cutaneous rash.
- Migratory polyarthritis or polyarthralgias.
- Intermittent abdominal pain.
- Nephritis.

General Considerations

Henoch-Schönlein purpura (HSP), the most common type of small vessel vasculitis in children, primarily affects boys 2–7 years of age. Occurrence is highest in the spring and fall, and upper respiratory infection precedes the diagnosis in two-thirds of children.

Leukocytoclastic vasculitis in HSP principally involves the small vessels of the skin, gastrointestinal tract, and kidneys, with deposition of IgA immune complexes. The most common and earliest symptom is palpable purpura, which results from extravasation of erythrocytes into the tissue surrounding the involved venules. Antigens from group A β-hemolytic streptococci and other bacteria,
viruses, drugs, foods, and insect bites have been proposed as inciting agents.

**Clinical Findings**

**A. Symptoms and Signs**

Skin involvement may be urticarial initially, progresses to a maculopapules, and coalesces to a symmetrical, palpable purpuric rash distributed on the legs, buttocks, and elbows. New lesions may continue to appear for 2–4 weeks, and may extend to involve the entire body. Two-thirds of patients develop migratory polyarthralgias or polyarthritis, primarily of the ankles and knees. Intermittent, sharp abdominal pain occurs in approximately 50% of patients, and hemorrhage and edema of the small intestine can often be demonstrated. Intussusception may develop. Approximately 25%–50% develop renal involvement in the second or third week of illness with either a nephritic or, less commonly, nephrotic picture. Hypertension may accompany the renal involvement. In males, testicular torsion may also occur, and neurologic symptoms are possible due to small vessel vasculitis.

**B. Laboratory Findings**

The platelet count is normal or elevated, and other screening tests of hemostasis and platelet function are typically normal. Urinalysis frequently reveals hematuria, and sometimes proteinuria. Stool may be positive for occult blood. The antistreptolysin O (ASO) titer is often elevated and the throat culture positive for group A β-hemolytic streptococci. Serum IgA may be elevated.

**Differential Diagnosis**

The rash of septicemia (especially meningococcemia) may be similar to skin involvement in HSP, although the distribution tends to be more generalized. The possibility of trauma should be considered in any child presenting with purpura. Other vasculitides should also be considered. The lesions of thrombotic thrombocytopenic purpura (TTP) are not palpable.

**Treatment**

Generally, treatment is supportive. NSAIDs may be useful for the arthritis. Corticosteroid therapy may provide symptomatic relief for severe gastrointestinal or joint manifestations but does not alter skin or renal manifestations. If culture for group A β-hemolytic streptococci is positive or if the ASO titer is elevated, a therapeutic course of penicillin is warranted.

**Prognosis**

The prognosis for recovery is generally good, although symptoms frequently (25%–50%) recur over a period of several months. In patients who develop renal manifestations, microscopic hematuria may persist for years. Progressive renal failure occurs in fewer than 5% of patients with HSP, with an overall fatality rate of 3%.

**2. Collagen Disorders**

Mild to life-threatening bleeding occurs with some types of Ehlers-Danlos syndrome, the most common inherited collagen disorder. Ehlers-Danlos syndrome is characterized by joint hypermobility, skin extensibility, and easy bruising. Coagulation abnormalities may sometimes be present, including platelet dysfunction and deficiencies of coagulation factors VIII, IX, XI, and XIII. However, bleeding and easy bruising, in most instances, relates to fragility of capillaries and compromised vascular integrity. Ehlers-Danlos syndrome types 4 and 6 are associated with at risk for aortic dissection and spontaneous rupture of aortic aneurysms. Surgery should be avoided for patients with Ehlers-Danlos syndrome, as should medications that induce platelet dysfunction.

**THROMBOTIC DISORDERS**

**General Considerations**

Although uncommon in children, thrombotic disorders are recognized with increasing frequency, particularly with heightened physician awareness and improved survival in pediatric intensive care settings. Several clinical conditions have a potential association with thrombotic events in childhood.

**Clinical Findings**

Initial evaluation of the child who has thrombosis includes an assessment for potential provoking factors, as well as a family history of thrombosis and early cardiovascular or cerebrovascular disease.

**A. Clinical Risk Factors**

Clinical risk factors are present in more than 90% of children with acute venous thromboembolism (VTE). These conditions include the presence of an indwelling vascular catheter, cardiac disease, infection, trauma, surgery, immobilization, collagen-vascular or chronic inflammatory disease, renal disease, sickle cell anemia, and malignancy.
Prospective findings employing serial radiologic evaluation as screening indicate that the risk of VTE is nearly 30% for short-term central venous catheters placed in the internal jugular veins. Retrospective data suggest that approximately 8% of children with cancer develop symptomatic VTE.

1. Inherited Thrombophilia (Hypercoagulable) States

A. Protein C deficiency—Protein C is a vitamin K-dependent protein that is activated by thrombin bound to thrombomodulin and inactivates activated factors V and VIII. In addition, activated protein C promotes fibrinolysis. Two phenotypes of hereditary protein C deficiency exist. Heterozygous individuals with autosomal dominant protein C deficiency often present with VTE as young adults, but the disorder may manifest during childhood or in later adulthood. In mild protein C deficiency, anticoagulant prophylaxis is typically limited to periods of increased prothrombotic risk. Homozygous or compound heterozygous protein C deficiency is rare but phenotypically severe. Affected children generally present within the first 12 hours of life with purpura fulminans (Figure 30–6) and/or VTE. Prompt protein C replacement by infusion of protein C concentrate (if unavailable) or FFP every 6–12 hours, along with therapeutic heparin administration, is recommended. Subsequent management requires chronic therapeutic anticoagulation, sometimes along with routine protein C concentrate infusion. Recurrent VTE is common, especially during periods of subtherapeutic anticoagulation or in the presence of conditions associated with increased prothrombotic risk.

B. Protein S deficiency—Protein S is a cofactor for protein C. Neonates with homozygous protein S deficiency have a course similar to those with homozygous or compound heterozygous protein C deficiency. Lifelong anticoagulation therapy is indicated in homozygous/severe deficiency, or in heterozygous individuals who have experienced recurrent VTE. Efforts must be made to distinguish these conditions from acquired deficiency, which can be antibody-mediated or secondary to an increase in C4b-binding protein induced by inflammation.

C. Antithrombin deficiency—Antithrombin, which is the most important physiologic inhibitor of thrombin, also inhibits activated factors IX, X, XI, and XII. Antithrombin deficiency is transmitted in an autosomal dominant pattern and associated with VTE, typically with onset in adolescence or young adulthood. Therapy for acute VTE involves replacement with antithrombin concentrate and therapeutic anticoagulation. The efficiency of heparin may be significantly diminished in the setting of severe antithrombin deficiency and it often requires supplementation of antithrombin via concentrate. Patients with homozygous/severe deficiency or recurrent VTE are maintained on lifelong anticoagulation.

D. Factor V Leiden mutation—An amino acid substitution in the gene coding for factor V results in factor V Leiden, a factor V polymorphism that is resistant to inactivation by activated protein C. The most common cause of activated protein C resistance in Caucasians, factor V Leiden is present in approximately 5% of the Caucasian population, 20% of Caucasian adults with deep vein thrombosis, and 40%–60% of those with a family history of VTE. VTE occurs in both heterozygous and homozygous individuals. In the former case, thrombosis is typically triggered by a clinical risk factor (or else develops in association with additional thrombophilia traits), whereas in the latter case, it is often spontaneous. Population studies suggest that the risk of incident VTE is increased two- to sevenfold in the setting of heterozygous factor V Leiden, 35-fold among heterozygous individuals taking the oral contraceptives, and 80-fold in those homozygous for factor V Leiden.

E. Prothrombin mutation—the 20210 glutamine to alanine mutation in the prothrombin gene is a relatively common polymorphism in Caucasians that enhances its activation to thrombin. In heterozygous form, this mutation is associated with a two- to threefold increased risk for incident VTE. This mutation also appears to modestly increase the risk for recurrent VTE.
HEMATOLOGIC DISORDERS

F. OTHER INHERITED DISORDERS—Qualitative abnormalities of fibrinogen (dysfibrinogenemias) are usually inherited in an autosomal dominant manner. Most individuals with dysfibrinogenemia are asymptomatic. Some patients experience bleeding, while others develop venous or arterial thrombosis. The diagnosis is suggested by a prolonged thrombin time with a normal fibrinogen concentration. Hyperhomocysteinemia can be an inherited or an acquired condition and is associated with an increased risk for both arterial and venous thromboses. In children, it may also serve as a risk factor for ischemic arterial stroke. Hyperhomocysteinemia is quite uncommon in the setting of dietary folate supplementation (as in the United States) and is observed almost uniquely in cases of renal insufficiency or metabolic disease (eg, homocystinuria). Methylene tetrahydrofolate reductase receptor mutations do not appear to constitute a risk factor for thrombosis in US children unless homocysteine is elevated.

Lipoprotein(a) is a lipoprotein with homology to plasminogen. In vitro studies suggest that lipoprotein(a) may both promote atherosclerosis and inhibit fibrinolysis. Some evidence to date suggests that elevated plasma concentrations of lipoprotein(a) are associated with an increased risk of VTEs and recurrent ischemic arterial stroke in children.

Increased factor VIII activity is a risk factor for incident VTE and is common among children with acute VTE. Most Elevation in factor VIII is acquired and may persist in the long-term, but it may also be inherited.

2. Acquired Disorders

A. ANTIPHOSPHOLIPID ANTIBODIES—The development of antiphospholipid antibodies is the most common form of acquired thrombophilia in children. Antiphospholipid antibodies, which include the lupus anticoagulant, anticardiolipin antibodies, and β2-glycoprotein-1 antibodies (among others) are common in acute childhood VTE. The lupus anticoagulant is demonstrated in vitro by its inhibition of phospholipid-dependent coagulation assays (eg, aPTT, dilute Russell viper venom time, hexagonal phase phospholipid neutralization assay), whereas immunologic techniques (eg, enzyme-linked immunosorbent assays) are often used to detect anticardiolipin and β2-glycoprotein-1 antibodies. Although common in persons with autoimmune diseases such as systemic lupus erythematosus, antiphospholipid antibodies may also develop following certain drug exposures, infection, acute inflammation, and lymphoproliferative diseases. Sometimes VTE and antiphospholipid antibodies may predate other signs of lupus. Viral illness is a common precipitant in children, and in many cases, the inciting infection may be asymptomatic.

When an antiphospholipid antibody persists for 12 weeks following the acute thrombotic event, the diagnosis of antiphospholipid syndrome (APS) is confirmed. Optimal duration of anticoagulation in this setting is unclear, such that current pediatric treatment guidelines recommend a 3-month to lifelong course.

B. DEFICIENCIES OF INTRINSIC ANTICOAGULANTS—Acquired deficiencies of proteins C and S and antithrombin may occur in the clinical context of antibodies (eg, protein S antibodies in acute varicella) or in excessive consumption, including sepsis, DIC, major-vessel or extensive VTE, and post–bone marrow transplant sinusoidal obstruction syndrome (formerly termed hepatic veno-occlusive disease). Pilot studies in children have suggested a possible therapeutic role for antithrombin or protein C concentrates in sepsis-associated DIC (eg, meningococcemia) and severe posttransplant sinusoidal obstruction syndrome.

C. ACUTE PHASE REACTANTS—As part of the acute-phase response, elevations in plasma fibrinogen concentration, plasma factor VIII, and platelet count may occur, all of which may contribute to an acquired prothrombotic state. Reactive thrombocytosis is rarely associated with VTEs in children when the platelet count is less than 1 million/μL.

B. Symptoms and Signs

Presenting features of thrombosis vary with the anatomic site, extent of vascular involvement, degree of vascular occlusion, and presence of end-organ dysfunction. The classic presentation of deep venous thrombosis of an upper or lower extremity is pain and acute or subacute extremity swelling, while that for pulmonary embolism commonly involves dyspnea and pleuritic chest pain, and in cerebral sinovenous thrombosis (CSVT) often includes severe or persistent headache, with or without neurologic deficit in otherwise well children. Arterial thrombosis of the lower extremity (eg, neonatal umbilical artery catheter–associated) as well as vasospasm without identified thrombosis, often manifests with diminished distal pulses and dusky discoloration of the limb.

C. Laboratory Findings

A comprehensive laboratory investigation for thrombophilia (ie, hypercoagulability) was recommended in 2002 by the International Society on Thrombosis and Hemostasis in order to disclose possible underlying congenital or acquired abnormalities that may affect acute or long-term management; however, there remains controversy and wide variation of practice. Recent trends favor thrombophilia testing in infants, children and adolescents with unprovoked thrombosis, and in neonates/children with non–catheter-related thrombosis and stroke. There is insufficient data to recommend routine thrombophilia testing in neonates or children with catheter-related thrombosis. When indicated, thrombophilia testing includes evaluation for intrinsic anticoagulant deficiency (proteins C and S and antithrombin),
procoagulant factor excess (eg, factor VIII), proteins and genetic mutations mediating enhanced procoagulant activity or reduced sensitivity to inactivation (antiphospholipid antibodies; factor V Leiden and prothrombin 20210 polymorphisms), biochemical mediators of endothelial damage (homocysteine), and markers or regulators of fibrinolysis (eg, D-dimer, plasminogen activator inhibitor-1, and lipoprotein[a]). Interpretation of procoagulant factor and intrinsic anticoagulant levels should take into account the age dependence of normal values for these proteins. Among these VTE risk factors, antiphospholipid antibodies and elevated levels of homocysteine and lipoprotein(a) have also been demonstrated as risk factors for arterial thrombotic ischemic events.

D. Imaging

Appropriate radiologic imaging is essential for objective documentation of thrombosis and to delineate the type (venous vs arterial), degree of occlusion, and extent (proximal and distal termini) of thrombosis. Depending on site, typical imaging modalities include compression ultrasound with Doppler, computed tomographic (CT) venography, magnetic resonance venography, and conventional angiography.

Treatment

Current guidelines for the treatment of first-episode VTE in children have been largely based on adult experience and include therapeutic anticoagulation for at least 3 months. During the period of anticoagulation, bleeding precautions should be followed, as previously described (see Treatment under Idiopathic Thrombocytopenic Purpura, earlier). Initial therapy for acute VTE employs continuous intravenous unfractionated heparin or subcutaneous injections of LMWH for at least 7 days, monitored by anti-Xa activity level to maintain anticoagulant levels of 0.3–0.7 or 0.5–1.0 IU/mL, respectively. Subsequent extended anticoagulant therapy is given with LMWH or daily oral warfarin, the latter agent monitored by the PT to maintain an international normalized ratio (INR) of 2.0–3.0. During warfarin treatment, the INR optimally should be within the therapeutic range for two consecutive days before discontinuation of heparin. Warfarin pharmacokinetics are affected by acute illness, numerous medications, and changes in diet, and can necessitate frequent monitoring. In children, warfarin dose is determined by age and weight. LMWH offers the advantage of infrequent monitoring but is far more expensive than warfarin. Anatomic contributions to venous stasis (eg, mastoiditis or depressed skull fracture as risk factors for CVST; congenital left iliac vein stenosis in DVT of proximal left lower extremity with May-Thurner anomaly) should be addressed to optimize response to anticoagulation.

In cases of limb- or life-threatening VTEs, including major proximal pulmonary embolus, and in cases of progressive VTE despite therapeutic anticoagulation, thrombolytic therapy (eg, tissue-type plasminogen activator) may be considered. Whether thrombolytic therapy may also reduce the risk of the postthrombotic syndrome (PTS) in children with veno-occlusive deep venous thrombosis of the proximal limbs in whom adverse prognostic biomarkers (ie, elevated factor VIII and D-dimer levels) are present at diagnosis needs prospective evaluation. In adolescent females, estrogen-containing contraceptives are relatively contraindicated in those with prior VTE if not using anticoagulation, particularly if an additional genetic cause for impairment of protein C pathway is disclosed.

Oral anticoagulants are now first-line therapy for adult acute VTE, and for extended anticoagulation. Phase 3 clinical trials in infants and children are ongoing.

Prognosis

Registries and cohort studies have suggested that recurrent VTE occurs in approximately 10% of children within 2 years. Persistent thrombosis is evident following completion of a standard therapeutic course of anticoagulation in up to 30% of children, with unclear clinical importance. Approximately one in four children with deep venous thrombosis involving the extremities develop post thrombotic syndrome, a condition of venous insufficiency of varying severity characterized by chronic skin changes, edema, and dilated collateral superficial venous formation, and often accompanied by functional limitation (pain with activities or at rest). Complete veno-occlusion and elevated levels of factor VIII and D-dimer at VTE diagnosis have been identified as prognostic factors for PTS among children with deep venous thrombosis affecting the limbs. The presence of homozygous anticoagulant deficiencies, multiple thrombophilia traits, or persistent antiphospholipid antibodies following VTE diagnosis has been associated with increased risk of recurrent VTE, leading to consideration of extended anticoagulation in these instances. In CSVT, failure to provide antithrombotic therapy has been associated with adverse neurologic outcome.

SPLENIC ABNORMALITIES

SPLENOMEGALY & HYPERSplenism

The differential diagnosis of splenomegaly includes the general categories of congestive splenomegaly, chronic infections, leukemia and lymphomas, hemolytic anemias, reticuloendothelioses, and storage diseases (Table 30–9).

Splenomegaly due to any cause may be associated with hypersplenism and the excessive destruction of circulating red cells, white cells, and platelets. The degree of cytopenia is variable and, when mild, requires no specific therapy. In other cases, the thrombocytopenia may cause life-threatening bleeding, particularly when the splenomegaly is secondary to portal hypertension and associated with esophageal varices or the consequence of a storage disease. In such cases, treatment with surgical splenectomy or with splenic embolization may be warranted. Although more commonly associated with acute enlargement, rupture of an enlarged spleen can be seen in more chronic conditions such as Gaucher disease.

ASPLENIA & SPLENECTOMY

Children who lack normal splenic function are at risk for sepsis, meningitis, and pneumonia due to encapsulated bacteria such as pneumococci, meningococcus and H influenzae. Such infections are often fulminant and fatal because of inadequate antibody production and impaired phagocytosis of circulating bacteria.

Congenital asplenia is usually suspected when an infant is born with abnormalities of abdominal viscera and complex cyanotic congenital heart disease. Howell-Jolly bodies are usually present on the peripheral blood smear, and the absence of splenic tissue is confirmed by technetium radionuclide scanning. The prognosis depends on the underlying cardiac lesions, and many children die during the first few months. Prophylactic antibiotics, usually penicillin, and pneumococcal conjugate, Hib, and meningococcal vaccines, are recommended.

The risk of overwhelming sepsis following surgical splenectomy is related to the child’s age and to the underlying disorder. Because the risk is highest when the procedure is performed earlier in life, splenectomy is usually postponed until after age 5 years. The risk of postsplenectomy sepsis is also greater in children with malignancies, thalassemias, and

is routine in several southern border states. Positive tests are and screening for Chagas disease was accepted in 2007 and testing) was mandated for HIV, HCV, and West Nile virus. a serologic test for syphilis (Table 30–10). Screening donor bodies to hepatitis B core antigen, hepatitis C, HIV-1 and 2, and human T-cell lymphotropic virus (HTLV) I and II; and a serologic test for syphilis (Table 30–10). Screening donor blood for viral genome (nucleic acid amplification [NAT] testing) was mandated for HIV, HCV, and West Nile virus. NAT testing for other viruses may be added in the future, and screening for Chagas disease was accepted in 2007 and is routine in several southern border states. Positive tests are repeated. Upon confirmation of a positive test, the unit in question is destroyed and the donor is notified and deferred from future donations. Many of the screening tests used are very sensitive and have a high rate of false-positive results. As a result, confirmatory tests have been developed to check the initial screening results and separate the false positives from the true positives, allowing for donors with repeat reactive screening tests on a specific donation to be reentered into the donor pool in the future if they meet specifications of an algorithm for further testing. Bacterial culture of apheresis or pooled platelet concentrates was added to the testing paradigm.

With these approaches, the risk of an infectious complication from blood components has been minimized (see Table 30–10). Recent addition of pathogen reduction techniques to blood components will provide an additional strategy to reduce transfusion transmitted infections and reduce the expense of additional testing for emerging infectious agents associated with blood transfusion. Autologous donation is recognized by some centers as a safe alternative to homologous blood. Issues of donor size limit the use of autologous donation difficult to apply to the pediatric population.

Primary CMV infections are significant complications of blood transfusion in transplant recipients, neonates, and immunodeficient individuals. Transmission of CMV can be avoided by using seronegative donors, apheresis platelet concentrates collected by techniques ensuring low numbers of residual white cells, or red cell or platelet products leukocyte-depleted by filtration (< 5 million WBCs per packed red cell unit or apheresis platelet concentrate equivalent).

### DONOR SCREENING & BLOOD PROCESSING: RISK MANAGEMENT

Minimizing the risks of transfusion begins by screening volunteer donors with a universal donor questionnaire designed to protect the recipient from transmission of infectious agents as well as other risks of transfusions. In addition, information defining high-risk groups whose behavior increases the possible transmission of HIV, hepatitis, and other diseases is provided, with the request that persons in these groups not donate blood. This screen also decreases risk of blood donation for the donor. Positive responses may result in temporary or permanent deferral from donation.

Before blood components can be released for transfusion, donor blood is screened for hepatitis B surface antigen; antibodies to hepatitis B core antigen, hepatitis C, HIV-1 and 2, and human T-cell lymphotropic virus (HTLV) I and II; and a serologic test for syphilis (Table 30–10). Screening donor blood for viral genome (nucleic acid amplification [NAT] testing) was mandated for HIV, HCV, and West Nile virus. NAT testing for other viruses may be added in the future, and screening for Chagas disease was accepted in 2007 and is routine in several southern border states. Positive tests are repeated.

Upon confirmation of a positive test, the unit in question is destroyed and the donor is notified and deferred from future donations. Many of the screening tests used are very sensitive and have a high rate of false-positive results. As a result, confirmatory tests have been developed to check the initial screening results and separate the false positives from the true positives, allowing for donors with repeat reactive screening tests on a specific donation to be reentered into

### STORAGE & PRESERVATION OF BLOOD & BLOOD COMPONENTS

Whole blood is routinely fractionated into packed red cells, platelets, and FFP or cryoprecipitate for most efficient use of all blood components. The storage conditions and biologic characteristics of the components are summarized in Table 30–11. The conditions provide the optimal environment to maintain appropriate recovery, survival, and function, and are different for each blood component. For example, red cells undergo dramatic metabolic changes during their 35- to 42-day storage, with a virtual disappearance of 2,3-DPG by day 14 of storage, a decrease in adenosine triphosphate, a gradual loss of intracellular potassium. After transfusion, in vivo recovery of greater than or equal to 80% transfused cells in red cells occurs even with older products. Fortunately, these changes are reversed readily in vivo within hours to days after the red cells are transfused. However, in certain clinical conditions, these effects may define the type of components used. For example, blood less than 5–7 days old would be preferred for exchange transfusion in neonates, red cell exchanges in older patients, or replacement of red cells in persons with severe cardiopulmonary disease to ensure adequate oxygen-carrying capacity. Storage time is not usually an issue when administering transfusions to those with chronic anemia.

If extracellular potassium in older packed red cells may present a problem, one may use blood less than 10 days old, making packed cells out of an older unit of whole blood or washing blood stored as packed cells.
Platelets are stored at 22°C for a maximum of 5 days; criteria for 7-day storage are being developed. At the extremes of storage, there should be at least a 60% recovery, a survival time that approximates turnover of fresh autologous platelets, and normalization of the bleeding time or PFA-100 in proportion to the peak platelet count. Frozen components, red cells, FFP, and cryoprecipitate are outdated at 10 years, 1 year, and 1 year, respectively. Frozen red cells retain the same biochemical and functional characteristics as the day they were frozen. FFP contains 80% or more of all of the clotting factors of fresh plasma. Factors VIII and XIII, vWF, and fibrinogen are concentrated in cryoprecipitate.

**PRETRANSFUSION TESTING**

Donated blood and recipient samples are tested for ABO and Rh(D) antigens and screened for auto- or alloantibodies in the plasma. The cross-match is required on any component that

| Whole blood            | 4°C for 35 days. RBC characteristics:  
|                        | • Survival: Recovery decreases during storage but is always > 70%–80%. Cells that circulate approximate normal survival.  
|                        | • Function: 2,3-DPG levels fall to undetectable after second week of storage. This defect is repaired within 12 h of transfusion.  
|                        | • Electrolytes: With storage, potassium increases in plasma. This rises to high levels after 2 wk of storage. | Contains RBCs and many plasma compounds of whole blood. Leukocytes and platelets lose activity or viability after 1–3 day under these conditions. Procoagulant clotting factors (particularly VIII and V) deteriorate rapidly during storage. Each unit has about 500 mL volume and Hct 36%–40%. | Oxygen-carrying capacity (anemia). Volume replacement for massive blood loss or severe shock. | Must be ABO-identical and cross-match-compatible. Infections. Febrile or hemolytic transfusion reactions. Alloimmunization to red cell, white cell, or platelet antigens. | During acute blood loss, as rapidly as tolerated. In other settings, 2–4 h. 10 mL/kg will raise Hct by 5% and support volume. |
| Packed red cells       | Same as for whole blood. Special preservative solutions allow storage for 42 day.  
|                        | Contains RBCs; most plasma removed in preparation. Status of leukocytes, clotting factors, and platelets same as for whole blood. Hct about 70%, volume 200–250 mL. May request tighter pack to give Hct 80%–90%. | Oxygen-carrying capacity. Acute trauma or bleeding or situations requiring intensive cardiopulmonary support (Hct < 25%–30%). Chronic anemia (Hct < 21%). | Same as for whole blood. | Same as for whole blood. | May be given as patient will tolerate, based on cardiovascular status over 2–4 h. Dose of 3 mL packed RBC/kg will raise Hct by 3%. If cardiovascular status is stable, give 10 mL/kg over 2–4 h. If unstable, use smaller volume or do packed RBC exchange. |
| Washed or filtered red cells | When cells are washed, there is a 24-h outdate. Up to that time, they have the same characteristics as for packed red cells. | Same as for packed red cells. | Same as packed red cells. Depending on technique used and extent of reduction of white blood cells, leukoreduced red cells may achieve the following:  
|                        | • Decrease in febrile reactions.  
|                        | • Decrease in transmission of CMV.  
<p>|                        | • Decrease in incidence of alloimmunization to white cell antigens. | Same as whole blood. Removal of white cells diminishes the risk of febrile reactions. Filtration with high-efficiency white cell filters may decrease rate of alloimmunization to white cell antigens and transmission of CMV. | Same as whole blood. | Same as for packed red cells. | Same as for packed red cells. |</p>

<tr>
<td><strong>Frozen red cells</strong></td>
<td>Packed red cells frozen in 40% glycerol solution at &lt; −65°C. After storage for 10 y, cells retain the same biochemical characteristics, function, and capacity for survival as on the day they were frozen; when thawed, 24-h outdate. Same as for packed red cells. Same as packed red cells. Useful for avoiding febrile reactions, decreasing transmission of CMV, autologous blood donation, and developing an inventory of rare red cell blood groups. Same as for whole blood. Risk of CMV transmission is at same level as using seronegative components. Same as for packed red cells.</td>
<td></td>
<td></td>
</tr>
<tr>
<td><strong>Fresh frozen plasma or 24 hour frozen plasma</strong></td>
<td>Plasma from whole blood stored at &lt; −18°C for up to 1 y. Contains &gt; 80% of all procoagulant and anticoagulant plasma proteins. Plasma separated from stored whole blood by 24 hours has similar characteristics. Replacement of plasma procoagulant and anticoagulant proteins. May provide “other” factors, eg, treatment of TTP. Use with deficiency of one or more clotting factors in association with bleeding, decreased liver production, or consumption (DIC) when the INR &gt; 1.5. For VIII, IX, VII, protein C, AT-III deficiency or inhibitors, use factor concentrates if available. Need not be cross-matched; should be type-compatible. Volume overload, infectious diseases, allergic reactions. Solvent detergent-treated plasma or donor-retested plasma units have decreased risk for viral transmission. As rapidly as tolerated by patient, but not &gt; 4 h. Dose: 10–15 mL/kg will increase level of all clotting factors by 10%–20%.</td>
<td></td>
<td></td>
</tr>
<tr>
<td><strong>Cryoprecipitate</strong></td>
<td>Produced by freezing fresh plasma to &lt; −65°C, then allowed to thaw 18 h at 4°C. After centrifugation, cryoprecipitable proteins are separated. May be stored at &lt; −18°C for up to 1 y. Contains factor VIII, vWF, fibrinogen, and fibronectin at concentrations greater than those of plasma. Also contains factor XIII, VIII &gt; 80 IU/pack, fibrinogen 100–350 mg/pack. Treatment of acquired or congenital deficiencies of fibrinogen, F XIII. Useful in making biologic glues that contain fibrinogen. Commercial clotting factor concentrates treatment of choice for factor VIII deficiency and vWD because sterilization procedures further reduce the risk of viral transmission. Same as for fresh frozen plasma. ABO agglutinins may also be concentrated and can give positive direct agglutination test if not type-specific. Cryoprecipitate can be given as a rapid infusion (30–60 min). Dose: ½ pack/kg body weight will increase factor VIII level by 80%–100% and fibrinogen by 200–250 mg/dL.</td>

CMV, cytomegalovirus; DPG, diphosphoglycerate; G-CSF, granulocyte colony–stimulating factor; Hct, hematocrit; RBC, red blood cell; TTP, thrombotic thrombocytopenic purpura; vWD, von Willebrand disease; vWF, von Willebrand factor.
contains red cells. In the major cross-match, washed donor red cells are incubated with the serum from the patient, and reactivity or agglutination is detected and graded after immediate centrifugation. The antiglobulin phase of the test may then be performed; Coombs reagent, which will detect the presence of IgG or complement on the surface of the red cells, is added to the mixture, and reactivity evaluated. In the presence of a negative antibody screen in the recipient, a negative immediate spin cross-match test confirms the compatibility of the blood and antiglobulin phase is not required. Further testing is required if the antibody screen or the cross-match is positive, and blood should not be given until the nature of the reactivity is delineated. An incompatible cross-match is evaluated first with a DAT or Coombs test to detect IgG or complement on the surfaces of the recipient’s red cells. The indirect antiglobulin test is also used to determine the presence of antibodies that will coat red cells or activate complement, and additional studies are completed to define the antibody.

**TRANSFUSION PRACTICE**

**General Rules**

Several rules should be observed in administering any blood component:

1. In final preparation of the component, no solutions should be added to the bag or tubing set except for normal saline (0.9% sodium chloride for injection, USP), ABO-compatible plasma, or other specifically approved expanders. Hypotonic solutions cause hemolysis of red cells, and, if these are transfused, a severe reaction will occur. Any reconstitution should be completed by the blood bank.

2. Transfusion products should be protected from contact with any calcium-containing solution (eg, lactated Ringer); recalcification and reversal of citrate effect will cause clotting of the blood component.

3. Blood components should not be warmed to a temperature greater than 37°C. If a component is incubated in a water bath, it should be enclosed in a watertight bag to prevent bacterial contamination of entry ports.

4. Whenever a blood bag is entered, the sterile integrity of the system is violated, and that unit should be discarded within 4 hours if left at room temperature or within 24 hours if the temperature is 4–6°C.

5. Transfusions of products containing red cells should not exceed 4 hours. Blood components in excess of what can be infused during this time period should be stored in the blood bank until needed.

6. Before transfusion, the blood component should be inspected visually for any unusual characteristics, such as the presence of flocculent material, hemolysis, or clumping of cells, and mixed thoroughly.

7. The unit and the recipient should be identified properly.

8. The administration set includes a standard 170- to 260-μm filter. Under certain clinical circumstances, an additional microaggregate filter may be used to eliminate small aggregates of fibrin, white cells, and platelets that will not be removed by the standard filter.

9. The patient should be observed during the entire transfusion, especially during the first 15 minutes. With the onset of any adverse symptoms or signs, the transfusion should be stopped, an evaluation initiated immediately, and the reaction reported promptly to the transfusion service. Untransfused components, blood samples from the patient and appropriate paperwork should also be submitted to the transfusion service.

10. When cross-match–incompatible red cells or whole blood unit(s) must be given to the patient (as with AIHA), a test dose of 10% of the total volume (not to exceed 50 mL) should be administered over 15–20 minutes; the transfusion is then stopped and the patient observed. If no changes in vital signs or the patient’s condition are noted, the remainder of the volume can be infused carefully.

11. Blood for exchange transfusion in the newborn period may be cross-matched with either the infant’s or the mother’s serum or plasma. If the exchange is for hemolysis, one unit of whole blood stored for less than 5–7 days will be adequate. If replacement of clotting factors is a key issue, packed red cells reconstituted with ABO type-specific FFP may be considered. Based on posttransfusion platelet counts, platelet transfusion may be considered. Other problems to be anticipated are acid–base derangements, hyponatremia, hyperkalemia, hypocalcemia, hypoglycemia, hypothermia, and hypervolemia or hypovolemia.

**Choice of Blood Component**

Several principles should be considered when deciding on the need for blood transfusion. Indications for blood or blood components must be well defined, and the patient’s medical condition, not just the laboratory results, should be the basis for the decision. Specific deficiencies exhibited by the patient (eg, oxygen-carrying capacity, thrombocytopenia) should be treated with appropriate blood components and the use of whole blood minimized. Information about specific blood components is summarized in Table 30–11. In general, very little is known about specific indications for blood component transfusion and outcomes. In recent years the criteria have become more restrictive for transfusion of any component. A recent review evaluates what is known and presents fertile areas for investigation (see Josephson et al).
A. Whole Blood
See Table 30–11.

B. Packed Red Blood Cells
See Table 30–11.

C. Platelets
The decision to transfuse platelets depends on the patient’s clinical condition, the status of plasma phase coagulation, the platelet count, the cause of the thrombocytopenia, and the functional capacity of the patient’s platelets. In the face of decreased production, clinical bleeding, and platelet counts less than 10,000/μL, the risk of severe, spontaneous bleeding is increased markedly. In the presence of these factors and in the absence heparin-induced thrombocytopenia, TTP, or antibody-mediated thrombocytopenia, transfusion may be considered. Under certain circumstances, especially with platelet dysfunction or treatment that inhibits the procoagulant system, transfusions at higher platelet counts may be necessary.

Transfused platelets are sequestered temporarily in the lungs and spleen before reaching their peak concentrations, 45–60 minutes after transfusion. A significant proportion of the transfused platelets never circulate but remain sequestered in the spleen. This phenomenon results in reduced recovery; under best conditions, only 60%–70% of the transfused platelets are accounted for when peripheral platelet count increments are used as a measure of response.

In addition to cessation of bleeding, two variables indicate the effectiveness of platelet transfusions. The first is platelet recovery, as measured by the maximum number of platelets circulating in response to transfusion. The practical measure is the platelet count at 1 hour after transfusion. In the absence of immune or drastic nonimmune factors that markedly decrease platelet recovery, one would expect a 7000/μL increment for each random donor unit and a 40,000–70,000/μL increment for each single-donor apheresis unit in a large child or adolescent. For infants and small children, 10 mL/kg of platelets will increase the platelet count by at least 50,000/μL. The second variable is the survival of transfused platelets. If the recovery is greater than 50,000/μL, transfused platelets will approach a normal half-life in the circulation. In the presence of increased platelet destruction, the lifespan may be shortened to a few days or a few hours. Frequent platelet transfusions may be required to maintain adequate hemostasis.

A particularly troublesome outcome in patients receiving long-term platelet transfusions is the development of a refractory state characterized by poor (≤ 20%) recovery or no response to platelet transfusion (as measured at 1 hour). Most (70%–90%) of these refractory states result from the development of alloantibodies directed against HLA antigens on the platelet. Platelets have Class I HLA antigens, and the antibodies are primarily against HLA A or B determinants. A smaller proportion of these alloantibodies (< 10%) may be directed against platelet-specific alloantigens. The most effective approach to prevent HLA sensitization is to use leukocyte-depleted components (< 5 million leukocytes per unit of packed red cells or per apheresis or 6–10 random donor unit concentrates). For the alloimmunized, refractory patient, the best approach is to provide HLA-matched platelets for transfusion. Platelet cross-matching procedures using HLA-matched or unmatched donors may be helpful in identifying platelet concentrates most likely to provide an adequate response.

D. Fresh Frozen Plasma
See Table 30–11.

E. Cryoprecipitate
See Table 30–11.

F. Granulocytes
With better supportive care over the past 20 years, the need for granulocytes in neutropenic patients with severe bacterial infections has decreased. Indications still remain for severe bacterial or fungal infections unresponsive to vigorous medical therapy in either newborns or older children with bone marrow failure, or patients with neutrophil dysfunction. Newer mobilization schemes using G-CSF and steroids in donors result in granulocyte collections with at least 50 billion neutrophils. This may provide a better product for patients requiring granulocyte support.

G. Apheresis Products and Procedures
Apheresis equipment allows one or more blood components to be collected while the rest are returned to the donor. Apheresis platelet concentrates, which have as many platelets as 6–10 units of platelet concentrates from whole blood donations, are one example; granulocytes are another. Apheresis techniques can also be used to collect hematopoietic stem cells that have been mobilized into the blood by cytokines (eg, G-CSF) or mononuclear cells for immunotherapy. Stem cells are used for allogeneic or autologous bone marrow transplantation. Blood cell separators can be used for the collection of single-source plasma or removal of a blood component that is causing disease. Examples include red cell exchange in sickle cell disease and plasmapheresis in Goodpasture syndrome, Guillain-Barré syndrome, or other antibody-mediated disorders.

Adverse Effects
The noninfectious complications of blood transfusions are outlined in Table 30–12. Most complications present a significant risk to the recipient.
Table 30–12. Adverse events following transfusions.

<thead>
<tr>
<th>Event</th>
<th>Pathophysiology</th>
<th>Signs and Symptoms</th>
<th>Management</th>
</tr>
</thead>
<tbody>
<tr>
<td>Acute hemolytic transfusion reaction</td>
<td>Preformed alloantibodies (most commonly to ABO) and infrequently autoantibodies cause rapid intravascular hemolysis of transfused cells with activation of clotting (DIC), activation of inflammatory mediators, and acute renal failure.</td>
<td>Fever, chills, nausea, chest pain, back pain, pain at transfusion site, hypotension, dyspnea, oliguria, hemoglobinuria.</td>
<td>The risk of this type of reaction overall is low (1:70,000–1:30,000), but the mortality rate is high (up to 40%). Stop the transfusion; maintain renal output with intravenous fluids and diuretics (furosemide or mannitol); treat DIC with heparin; and institute other appropriate supportive measures.</td>
</tr>
<tr>
<td>Delayed hemolytic transfusion reaction</td>
<td>Formation of alloantibodies after transfusion and resultant destruction of transfused red cells, usually by extravascular hemolysis.</td>
<td>Jaundice, anemia. A small percentage may develop chronic hemolysis.</td>
<td>Detection, definition, and documentation (for future transfusions). Supportive care. Risk, &lt; 5% of transfused patients may develop alloantibody; hemolysis, 1:11,000–1:2500. Supportive. Leukocyte-reduced products decrease reactions. Risk per transfusion, 1:100 transfusions.</td>
</tr>
<tr>
<td>Febrile reactions</td>
<td>Usually caused by leukoagglutinins in recipient, cytokines, or other biologically active compounds.</td>
<td>Fever. May also involve chills.</td>
<td></td>
</tr>
<tr>
<td>Allergic reactions</td>
<td>Most causes not identified. In IgA-deficient individuals, reaction occurs as a result of antibodies to IgA.</td>
<td>Itching, hives, and occasionally chills and fever. In severe reactions, may see signs of anaphylaxis: dyspnea, pulmonary edema.</td>
<td>Mild to moderate reactions: diphenhydramine. More severe reactions: epinephrine subcutaneously and steroids intravenously. Risk for mild to moderate allergic reactions, 1:100. Severe anaphylactic reactions, 1:50,000—1:20,000.</td>
</tr>
<tr>
<td>Transfusion-related acute lung injury</td>
<td>Acute lung injury occurring within 6 h after transfusion. Two sets of factors interact to produce the syndrome. Patient factors: infection, surgery, cytokine therapy. Blood component factors: lipids, antibodies, cytokines. Two groups of factors interact during transfusion to result in lung injury indistinguishable from ARDS.</td>
<td>Tachypnea, dyspnea, hypoxia. Diffuse interstitial markings. Cardiac evaluation normal.</td>
<td>May consider younger products: packed red blood cells ≤ 2 wk, platelets ≤ 3 days, washing components to prevent syndrome. Management: supportive care. Risk, 1:2000–1:3000 per transfusion. Current preventive procedures include avoiding donors at risk for alloimmunization: use of male-only FFP or white blood cell antibody-negative apheresis FFP or platelet products.</td>

for modifying future treatment regimens to decrease morbidity. A guide for caring for childhood cancer survivors is now available to medical providers as well as families and details suggested examinations and late effects by type of chemotherapy received.

MAJOR PEDIATRIC NEOPLASTIC DISEASES

ACUTE LYMPHOBLASTIC LEUKEMIA

General Considerations

Acute lymphoblastic leukemia (ALL) is the most common malignancy of childhood, accounting for about 25% of all cancer diagnoses in patients younger than 15 years. The worldwide incidence of ALL is about 1,250,000 children per year, including 3000 children per year in the United States. The peak age at onset is 4 years; 85% of patients are diagnosed between ages 2 and 10 years. Children with Down syndrome have a 14-fold increase in the overall rate of leukemia.

ALL results from uncontrolled proliferation of immature lymphocytes. Its cause is unknown, and genetic factors may play a role. Leukemia is defined by the presence of more than 25% malignant hematopoietic cells (blasts) in the bone marrow aspirate. Leukemic blasts from the majority of cases of childhood ALL have an antigen on the cell surface called the common ALL antigen (CALLA). These blasts derive from B-cell precursors early in their development, called B-precursor ALL. Less commonly, lymphoblasts are of T-cell origin or of mature B-cell origin. Over 70% of children...
receiving aggressive combination chemotherapy and early presymptomatic treatment to the central nervous system (CNS) are now cured of ALL.

► Clinical Findings

A. Symptoms and Signs

Presenting complaints of patients with ALL include those related to decreased bone marrow production of red blood cells (RBCs), white blood cells (WBCs), or platelets and to leukemic infiltration of extramedullary (outside bone marrow) sites. Intermittent fevers are common, as a result of either cytokines induced by the leukemia itself or infections secondary to leukopenia. Many patients present due to bruising or pallor. About 25% of patients experience bone pain, especially in the pelvis, vertebral bodies, and legs.

Physical examination at diagnosis ranges from virtually normal to highly abnormal. Signs related to bone marrow infiltration by leukemia include pallor, petechiae, and purpura. Hepatomegaly and/or splenomegaly occur in over 60% of patients. Lymphadenopathy is common, either localized or generalized to cervical, axillary, and inguinal regions. The testes may occasionally be unilaterally or bilaterally enlarged secondary to leukemic infiltration. Superior vena cava syndrome is caused by mediastinal adenopathy compressing the superior vena cava. A prominent venous pattern develops over the upper chest from collateral vein enlargement. The neck may feel full from venous engorgement. The face may appear plethoric, and the periorbital area may be edematous. A mediastinal mass can cause tachypnea, orthopnea, and respiratory distress. Leukemic infiltration of cranial nerves may cause cranial nerve palsies with mild nuchal rigidity. The optic fundi may show exudates of leukemic infiltration and hemorrhage from thrombocytopenia. Anemia can cause a flow murmur, tachycardia, and, rarely, congestive heart failure.

B. Laboratory Findings

A complete blood count (CBC) with differential is the most useful initial test because 95% of patients with ALL have a decrease in at least one cell type (single cytopenia): neutropenia, thrombocytopenia, or anemia with most patients having a decrease in at least two blood cell lines. The WBC count is low or normal (= 10,000/μL) in 50% of patients, but the differential shows neutropenia (absolute neutrophil count < 1000/μL) along with a small percentage of blasts amid normal lymphocytes. In 30% of patients the WBC count is between 10,000/μL and 50,000/μL; in 20% of patients it is over 50,000/μL, occasionally higher than 300,000/μL. Blasts are usually readily identifiable on peripheral blood smears from patients with elevated WBC counts. Peripheral blood smears also show abnormalities in RBCs, such as teardrops. Most patients with ALL have decreased platelet counts (< 150,000/μL) and decreased hemoglobin (< 11 g/dL) at diagnosis. In approximately 1% of patients diagnosed with ALL, CBCs and peripheral blood smears are entirely normal, but patients have bone pain that leads to bone marrow examination. Serum chemistries, particularly uric acid and lactate dehydrogenase (LDH), are often elevated at diagnosis as a result of cell breakdown.

The diagnosis of ALL is made by bone marrow examination, which shows a homogeneous infiltration of leukemic blasts replacing normal marrow elements. The morphology of blasts on bone marrow aspirate can usually distinguish ALL from acute myeloid leukemia (AML). Lymphoblasts are typically small, with cell diameters of approximately two erythrocytes. Lymphoblasts have scant cytoplasm, usually without granules. The nucleus typically contains no nucleoli or one small, indistinct nucleolus. Immunophenotyping of ALL blasts by flow cytometry helps distinguish precursor B-cell ALL from T-cell ALL or AML. Histochemical stains specific for myeloblastic and monoblastic leukemias (myeloperoxidase and nonspecific esterase) distinguish ALL from AML. About 5% of patients present with CNS leukemia, which is defined as a cerebrospinal fluid (CSF) WBC count greater than 5/μL with blasts present on cytocentrifuged specimen.

C. Imaging

Chest radiograph may show mediastinal widening or an anterior mediastinal mass and tracheal compression secondary to lymphadenopathy or thymic infiltration, especially in T-cell ALL. Abdominal ultrasound may show kidney enlargement from leukemic infiltration or uric acid nephropathy as well as intra-abdominal adenopathy. Plain radiographs of the long bones and spine may show demineralization, periosteal elevation, growth arrest lines, or compression of vertebral bodies. Although these findings may suggest leukemia, they are not diagnostic.

► Differential Diagnosis

The differential diagnosis, based on the history and physical examination, includes chronic infections by Epstein-Barr virus (EBV) and cytomegalovirus (CMV), causing lymphadenopathy, hepatosplenomegaly, fevers, and anemia. Prominent petechiae and purpura suggest a diagnosis of immune thrombocytopenic purpura. Significant pallor could be caused by transient erythroblastopenia of childhood, autoimmune hemolytic anemia, or aplastic anemia. Fevers and joint pains, with or without hepatosplenomegaly and lymphadenopathy, suggest juvenile rheumatoid arthritis (JRA). The diagnosis of leukemia usually becomes
Treatment
A. Specific Therapy

Intensity of treatment is determined by specific prognostic features present at diagnosis, the patient’s response to therapy, and specific biologic features of the leukemia cells. The majority of patients with ALL are enrolled in clinical trials designed by clinical groups and approved by the National Cancer Institute; the largest group is COG. The first month of therapy consists of induction, at the end of which over 95% of patients exhibit remission on bone marrow aspirates by morphology. The drugs most commonly used in induction include oral prednisone or dexamethasone, intravenous vincristine, daunorubicin, intramuscular or intravenous asparaginase, and intrathecal methotrexate.

Consolidation is the second phase of treatment, during which intrathecal chemotherapy along with continued systemic therapy and sometimes cranial radiation therapy are given to kill lymphoblasts “hiding” in the meninges. Several months of intensive chemotherapy follows consolidation, often referred to as intensification. This intensification has led to improved survival in pediatric ALL.

Maintenance therapy can include daily oral mercaptopurine, weekly oral methotrexate, and, often, monthly pulses of intravenous vincristine or oral prednisone or dexamethasone. Intrathecal chemotherapy, either with methotrexate alone or combined with cytarabine and hydrocortisone, is usually given every 2–3 months.

Chemotherapy has significant potential side effects. Patients need to be monitored closely to prevent drug toxicities and to ensure early treatment of complications. The duration of treatment ranges between 2.2 years for girls and 3.2 years for boys in COG trials. Treatment for ALL is tailored to prognostic, or risk, groups. A child aged 1–9 years with a WBC count below 50,000/μL at diagnosis of pre B ALL and without poor biologic features [(t(9;22) or an 11q23 rearrangement)] is considered to be at “standard risk” and receives less intensive therapy than a “high-risk” patient who has a WBC count at diagnosis over 50,000/μL or is 10 years of age or greater. An infant less than 1 year at diagnosis would be considered very high risk and receive even more intensive chemotherapy. Also important is the patient’s response to treatment determined by minimal residual disease (MRD) monitoring. This risk-adapted treatment approach has significantly increased the cure rate among patients with less favorable prognostic features by allowing for early intensification while minimizing treatment-related toxicities in those with favorable features. Bone marrow relapse is usually heralded by an abnormal CBC, either during treatment or following completion of therapy.

The CNS and testes are sanctuary sites of extramedullary leukemia. Currently, about one-third of all ALL relapses are isolated to these sanctuary sites. Systemic chemotherapy does not penetrate these tissues as well as it penetrates other organs. Thus, presymptomatic intrathecal chemotherapy is a critical part of ALL treatment, without which many more relapses would occur in the CNS, with or without bone marrow relapse. The majority of isolated CNS relapses are diagnosed in an asymptomatic child at the time of routine intrathecal injection, when CSF cell count and differential show an elevated WBC with leukemic blasts. Occasionally, symptoms of CNS relapse develop: headache, nausea and vomiting, irritability, nuchal rigidity, photophobia, changes in vision, and cranial nerve palsies. Currently, testicular relapse occurs in less than 5% of boys. The presentation of testicular relapse is usually unilateral painless testicular enlargement, without a distinct mass. Routine follow-up of boys both on and off treatment includes physical examination of the testes.

Bone marrow transplantation, now called hematopoietic stem cell transplantation (HSCT), is rarely used as initial treatment for ALL, because most patients are cured with chemotherapy alone. Patients whose blasts contain certain chromosomal abnormalities, hypodiploidy (< 44 chromosomes), and patients with a very slow response to therapy may have a better cure rate with early HSCT from a human leukocyte antigen (HLA)-DR–matched sibling donor, or perhaps a matched unrelated donor, than with intensive chemotherapy alone. HSCT cures about 50% of patients who relapse, provided that a second remission is achieved with chemotherapy before transplant. Children who relapse more than 1 year after completion of chemotherapy (late relapse) may be cured with intensive chemotherapy without HSCT.

Several new biologic agents, including tyrosine kinase inhibitors and immunotoxins, are currently in various stages of research, development, and in chemotherapeutic trials. Some of these therapies may prove relevant for future treatment of poor risk or relapsed ALL.

Several years ago, Imatinib, a tyrosine kinase inhibitor (TKI), directed against the Philadelphia chromosome (Ph+) protein product, was combined in a backbone of intensive ALL therapy for Ph+ ALL in pediatric patients. The preliminary results of this trial showed a 3-year event-free survival (EFS) of 78% compared to about 50% in historical controls. An ongoing trial for COG in Ph+ ALL is incorporating a newer, more targeted TKI, Dasatinib,
into a very similar intensive chemotherapy background with the goal of improving EFS further for this select group of patients. As more is understood about the biology of ALL, further therapy will likely include more of these targeted agents.

**B. Supportive Care**

Tumor lysis syndrome, which consists of hyperkalemia, hyperuricemia, hyperphosphatemia, should be anticipated when treatment is started. Maintaining brisk urine output with intravenous fluids plus/minus alkalization of urine with intravenous sodium bicarbonate and treating with oral allopurinol are appropriate steps in managing tumor lysis syndrome. Rasburicase is indicated for severe tumor lysis syndrome with initial high uric acid values or high WBC at presentation. Serum levels of potassium, phosphorus, and uric acid should be monitored. If superior vena caval or superior mediastinal syndrome is present, general anesthesia is contraindicated temporarily and until there has been some decrease in the mass. If hyperleukocytosis (WBC count > 100,000/µL) is accompanied by hyperviscosity with symptoms of respiratory distress and/or mental status changes, leukopheresis may be indicated to rapidly reduce the number of circulating blasts and minimize the potential thrombotic or hemorrhagic CNS complications. Throughout the course of treatment, all transfused blood and platelet products should be irradiated to prevent graft-versus-host disease (GVHD) from the transfused lymphocytes. Whenever possible, blood products should be leuko-depleted to minimize CMV transmission, transfusion reactions, and sensitization to platelets.

Due to the immunocompromised state of the patient with ALL, bacterial, fungal, and viral infections are serious and can be life-threatening or fatal. During the course of treatment, fever (temperature = 38.3°C) and neutropenia (absolute neutrophil count < 500/µL) require prompt assessment, blood cultures from each lumen of a central line, and prompt treatment with empiric broad-spectrum antibiotics. Patients receiving ALL treatment must receive prophylaxis against *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*). Trimethoprim-sulfamethoxazole given twice each day on Day 1 and then daily for 2 or 3 consecutive days per week is the drug of choice. Patients nonimmune to varicella are at risk for very serious—even fatal—infection. Such patients should receive varicella-zoster immune globulin (VZIG) within 72 hours after exposure and treatment with intravenous acyclovir for active infection.

**Prognosis**

Cure rates depend on specific prognostic features present at diagnosis, biologic features of the leukemic blast, and the response to therapy. Two of the most important features are WBC count and age. Children aged 1–9 years whose diagnostic WBC count is less than 50,000/µL, standard risk ALL, have an EFS greater than 90% range, while children 10 years or older have an EFS of approximately 88%. MRD measurements are now frequently used to determine both the rapidity of response as well as the depth of remission attained at the end of induction (first 4–6 weeks of therapy). Patients with very low levels of MRD at the end of induction will likely have a superior EFS as compared to other patients with similar initial risk factors but a higher MRD level. On the flip side, by identifying patients with higher MRD at end induction, more intensified therapy can be delivered in order to reduce the MRD and thus, improve the EFS.

Certain chromosomal abnormalities present in the leukemic blasts at diagnosis influence prognosis. Patients with t(9;22), the Philadelphia chromosome, had a poor chance of cure in the past but as discussed earlier in this chapter, now have improved outcome with the incorporation of a directed TKI. Likewise, infants younger than 6 months with 11q23 rearrangements have a poor chance of cure with conventional chemotherapy. In contrast, patients whose blasts are hyperdiploid (containing > 50 chromosomes instead of the normal 46) with trisomies of chromosomes 4, and 10, and patients whose blasts have a t(12;21) and *ETV6-AML1* rearrangement have a greater chance of cure, approaching 95%–97% EFS, than do children without these characteristics.
